The Human Capital Index

2020 UPDATE

Human Capital in the Time of COVID-19

WORLD BANK GROUP
The Human Capital Index is a collaboration between the Human Development Practice Group and the Development Economics Group of the World Bank. The 2020 update was led by Roberta Gatti and Aart Kraay and produced by Paul Corral, Nicola Dehnen, Ritika D’Souza and Juan Mejalenko. Noam Angrist, Syedah Aroob Iqbal, and Harry Patrinos updated the Harmonized Test Score outcomes. We are grateful to Pablo Ariel Acosta, Rita Kullberg Almeida, D. H. C. Aturupane, Anne Margreth Bakilana, Tekabe Ayalew Belay, Paolo Belli, Livia M. Benavides, Kamel Braham, Fadila Caillaud, Carine Clert, Jorge Coarasa, Gabriel Demombynes, Heba Elgazzar, Sameh El-Saharty, Stefan Emblad, Lire Ersado, Antonio Giuffrida, Inaam Ul Haq, Susanna Hayrapetyan, Samira Ahmed Hillis, Camilla Holmemo, Keiko Inoue, Timothy Johnston, Pierre Joseph Kamano, Olga Khan, Christophe Lemiere, Yasuhiro Matsuda, Muna Meky, Sophie Naudeau, Dorota Agata Nowak, Emre Ozaltin, Aleksandra Posarac, Maria Laura Sanchez Puerta, Hnin Hnin Pyne, Jamele P. Rigolini, Rafael Rofman, Cristina Isabel Panasco Santos, Aparnaa Somanathan, Lars Sondergaard, Michel Welmond, William Wiseman, Ruslan Yemtsov and Xiaoqing Yu for careful data review.

This report was written by a core team led by Roberta Gatti and including Paul Corral, Nicola Dehnen, Ritika D’Souza and Juan Mejalenko. Steven Pennings wrote the chapter on Human Capital Utilization. This report benefitted from Aart Kraay’s advice and from analytical inputs by: Daniel Halim (gender analysis), Amer Hasan and Fiona Mackintosh (case studies narrative), Jigyasa Sharma (on fragility), Joao Pedro de Azevedo and Diana Goldberg (COVID-19 impact on learning-adjusted years of schooling), Dina Abu-Ghaida and Mohamed Audah (schooling in Syria), Alejandro de la Fuente (schooling in Sierra Leone), Chloé Desjonquères (learning progress in Ceará), Alina Sava and Lars Sondergaard (schooling in Romania), Utz Pape (Rapid Response Phone Surveys), Halsey Rogers (Challenges in test-score comparison over time), Saskia de Pee and Cecilia Garzón (World Food Program) and Naveed Akbar (Benazir Income Support Programme, Government of Pakistan) and Emanuela Galasso, Lisa Saldanha, Meera Shekar, Marie-Chantal Uwanyiligira, and Kavita Watsa (cross-sectoral approaches to stunting). We are indebted to David Weil for his overarching guidance. We are grateful to our peer reviewers Shubham Chaudhuri, Rachel Glennerster, William Maloney, and David Weil for their insightful views and to Deon Filmer for his detailed comments on earlier versions of this draft. We thank Kathleen Beegle, Hana Brixii, Emanuela Galasso, Ramesh Govindaraj, Ambar Narayan, Meera Shekar, Sharad Tandon, Tara Vishwanath, and Michael Weber for thoughtful comments and conversations. We are grateful to Alex Irwin for his outstanding editing touch, to Chloé Desjonquères for efficiently managing the report’s production process, and to Ruben Conner, Mary Fisk, Sebastian Insfran, and Andres Yi Chang for their careful read of the report. Finally, we are also grateful to Luis Eduardo San Martin and Luiza Andrade from the DIME Analytics team for a thorough code review.

This Human Capital Index update was developed under the strategic guidance of Mari Pangestu, Annette Dixon, and Mamta Murthi and benefitted from the views of Nadir Mohammed and Alberto Rodriguez.

Executive Summary

The Human Capital Index (HCI) is an international metric that benchmarks key components of human capital across countries. Measuring the human capital that a child born today can expect to attain by her 18th birthday, the HCI highlights how current health and education outcomes shape the productivity of the next generation of workers. In this way, it underscores the importance for governments and societies of investing in the human capital of their citizens. The HCI was launched in 2018 as part of the Human Capital Project (HCP), a global effort to accelerate progress towards a world where all children can achieve their full potential.

Over the past decade, many countries have made important progress in improving human capital. Today, however, the COVID-19 pandemic threatens to reverse many of those gains. Urgent action is needed to protect hard-won advances in human capital, particularly among the poor vulnerable. Designing the needed interventions, targeting them to achieve the highest effectiveness, and navigating difficult trade-offs in times of reduced fiscal space, makes investing in better measurement of human capital more important than ever.

Human capital consists of the knowledge, skills, and health that people accumulate over their lives. People’s health and education have undeniable intrinsic value, and human capital also enables people to realize their potential as productive members of society. More human capital is associated with higher earnings for people, higher income for countries, and stronger cohesion in societies. It is a central driver of sustainable growth and poverty reduction.

This report accompanies the release of 2020 data on the HCI. Building on momentum from the first edition in 2018, the 2020 issue updates the index using new and expanded data for each of the HCI components through March 2020. As such, the report provides a snapshot of the state of human capital before COVID-19 and a baseline to track the pandemic’s impacts on human capital.

COVID-19 struck at a time when the world was healthier and more educated than ever. Yet, data presented in this report reveal that substantial human-capital shortfalls and equity gaps existed before the crisis. Worldwide, a child born just before the advent of COVID-19 could expect to achieve on average just 56 percent of her potential productivity as a future worker. Gaps in human capital remain especially deep in low-income countries and those affected by violence, armed conflict, and institutional fragility. Expanded sex-disaggregated data show that girls currently enjoy a slight edge over boys in human capital accumulation in most countries, reflecting in part a female biological advantage early in life. However women continue to be at a substantial disadvantage in many dimensions of human capital that are not captured by the HCI’s components, including participation in economic life.
In addition to describing HCI data and methodology, this report documents the evolution of human capital over the last decade. Human capital outcomes progressed in almost all countries by about 4 percent on average during this period, thanks primarily to better health and increased access to schooling. However, many countries struggled to improve learning outcomes, as educational quality often failed to keep pace with gains in enrollment. The various dimensions of human capital improved with economic development, and they did so at a surprisingly similar pace across country income groups. Progress was only slightly faster in low-income countries, which are further away from the frontier of full health and education.

The trajectories of individual countries differed considerably, including in how human-capital gains were distributed across the socio-economic spectrum within each country. In some contexts, the most disadvantaged groups scored the greatest gains. In others, poorer and richer families benefitted equally. Along with broad economic development, specific policies contributed to some countries’ progress in human capital. Effective policies included expanding the population coverage of health services, notably for maternal and child health; bolstering nutrition and access to sanitation; making school more affordable; and providing financial support to vulnerable families through mechanisms such as cash transfer programs and insurance. Strong gains were more likely in countries that were able to maintain commitment to reform across political cycles and to adopt an evidence-based, whole-of-society approach to policymaking.

These same elements will be essential to protect human capital in the face of the COVID-19 crisis. While data on COVID-19’s impacts on human-capital outcomes are only beginning to emerge, simulations conducted for this report suggest that school closures combined with family hardship are significantly affecting the accumulation of human capital for the current generation of school-age children. The impacts appear comparable in magnitude to the gains that many countries achieved during the previous decade, suggesting that the pandemic may roll back many years’ worth of human-capital progress. In parallel, COVID-19’s disruption of health services, losses in income, and worsened nutrition are expected to increase child mortality and stunting, with effects that will be felt for decades to come.

The HCI can be a useful tool to track such losses and guide policy to counter them, since the index is based on robust markers for key stages of human-capital accumulation in the growth trajectory of a child. However, the five components of the HCI do not cover all the important aspects of the accumulation and productive use of human capital. In particular, the index is silent on the opportunities to use accumulated human capital in adulthood through meaningful work. In many countries, a sizable fraction of today’s young people may not be employed when they become adults. Even if they find employment, they may not hold jobs where they can use their skills and cognitive abilities to increase their productivity. Recognizing the salience of such patterns for how human capital gains are translated into economic progress and shared prosperity, this report analyzes two measures that augment the HCI to account for the utilization of human capital. These measures provide insight on further margins that countries can explore to boost their long-term growth and productivity. Both utilization measures suggest that human capital is particularly underutilized in middle-income countries. A key message is that human capital is also strikingly underutilized for women in many settings: the gender gap in employment rates (a basic measure of utilization) is 20 percentage points on average worldwide, but exceeds 40 percentage points in South Asia and the Middle East and North Africa.
By bringing salience to the productivity implications of shortfalls in health and education, the HCI has not only clarified the importance of investing in human capital, but also highlighted the role that measurement can play in catalyzing consensus for reform. Better measurement enables policy makers to design effective interventions and target support to those who are most in need, which is often where interventions yield the highest payoffs. Investing in better measurement and data use now is a necessity, not a luxury. In the immediate, it will guide pandemic containment strategies and support for the most affected. In the medium term, better curation and use of administrative, survey, and identification data will be essential to guide policy choices in an environment of limited fiscal space and competing priorities.

Today, hard-won human capital gains in many countries are at risk. But countries can do more than just work to recover the lost ground. Ambitious, evidence-driven policy measures in health, education, and social protection can pave the way for today’s children to surpass the human-capital achievements and quality of life of the generations that preceded them.

To protect and extend earlier human-capital gains, policymakers need to expand health service coverage and quality among marginalized communities, boost learning outcomes together with school enrollments, and support vulnerable families with social protection measures adapted to the scale of the COVID-19 crisis. Informed by rigorous measurement, bold policies can drive a resilient recovery from the pandemic and open a future in which rising generations will be able to develop their full potential and use it to tackle the vast challenges that still lie ahead for countries and the world: from ending poverty to preventing armed conflict to controlling climate change. COVID-19 has underscored the shared vulnerability and common responsibility that today link all nations. Fully realizing the creative promise embodied in each child has never been more important.
Overview

The Human Capital Index (HCI) measures the human capital that a child born today can expect to attain by her 18th birthday, given the risks of poor health and poor education prevailing in her country. The index incorporates measures of different dimensions of human capital: health (child survival, stunting and adult survival rates) and the quantity and quality of schooling (expected years of schooling and international test scores). Human capital has intrinsic value that is undeniably important, but difficult to quantify. This in turn makes it challenging to combine its different components into a single measure. The HCI uses global estimates of the economic returns to education and health to create an integrated index that captures the expected productivity of a child born today as a future worker, relative to a benchmark – the same for all countries – of complete education and full health.

The HCI 2020 Update

The 2020 update of the HCI incorporates the most recent available data to report HCI scores for 174 countries, adding 17 new countries to the index relative to the 2018 edition. The 2020 update uses new and expanded data for each of the HCI components, available as of March 2020. As in 2018, data were obtained from official sources and underwent a careful process of review and curation. Given the timing of data collection, this update can serve as a benchmark of the levels of human capital accumulation that existed immediately prior to the onset of the COVID-19 pandemic.

Globally, the HCI 2020 shows that, before the pandemic struck, a child could expect to attain an average of 56 percent of her potential productivity as a future worker. This global average masks considerable variation across regions and economies. For instance, a child born in a low-income country could expect to be 37 percent as productive as if she had full education and full health. For a child born in a high-income country, this figure is 70 percent.

Income Alone Does Not Explain Country Differences in Human Capital

What explains these variations in human capital outcomes? While the correlation between HCI and gross domestic product (GDP) per capita is strong, human capital does not always move in lockstep with economic development. Countries like Burundi, Estonia, Kyrgyz Republic, Uzbekistan, and Vietnam have outcomes

---

1 The HCI was introduced in World Bank (2018a, 2018b), and the methodology of the HCI is detailed in Kraay (2019).
that are higher than predicted by their GDP per capita. Conversely, in a number of countries, human capital is lower than per capita income would suggest. Among these are several resource-rich countries, where human capital development has not yet matched the potential that one would anticipate, given these countries’ wealth.

Differences in the quantity and quality of schooling account for the largest part of HCI differences across country-income groups. Of the 33 percentage-point difference between the scores of the average low- and high-income country, almost 25 percentage points are accounted for by the differences in learning-adjusted years of school, a measure which combines expected years of school with learning as measured by harmonized test scores (i.e. test scores that are made comparable across countries).

While education drives HCl differences across country-income groups, education’s contribution to gaps within these groups varies by income level. For instance, education accounts for roughly 90 percent of the difference between high and low performers within high-income country groups, but only 60 percent within the group of low-income economies. In contrast, differences in child survival rates account for less of the difference in HCl scores among high-income countries, largely because child mortality is low across these countries. The same is true for health differences, which explain a lower share of country differences in the HCl as one moves from low- to higher-income groups, since health outcomes tend to be uniformly better as countries get richer.2

Human capital outcomes also vary for girls and boys. A disaggregation of the HCl by gender—now available for 153 of the 174 included countries—shows that human capital is slightly higher among girls than boys in most countries. Girls are not only catching up to but outperforming boys in expected years of schooling and learning outcomes in some regions. For example, in the Middle East and North Africa, girls can expect to complete more than half of an additional learning-adjusted year of school compared with boys. However, the reverse is true in Sub-Saharan Africa and in South Asia.

Investing in human capital enhances social cohesion and equity while strengthening people’s trust in institutions. Nowhere is this more important than in countries grappling with fragility and conflict. External shocks such as armed conflict and natural disasters have destructive impacts on both countries’ existing human capital stock and on the process of building new human capital. Evidence increasingly suggests that, for armed conflict as well as famine, these negative effects can persist for decades and even across generations. This weakens the core of sustainable and equitable economic development.

Unfortunately, yet unsurprisingly, the HCl 2020 indicates that, on average, countries impacted by fragility, conflict, and violence have lower HCl values, compared to the rest of the world. In particular, the seven countries with the lowest HCl 2020 scores are also on the World Bank’s current list of fragile and conflict-affected situations (FCS). This adds to the urgency of addressing human-capital gaps in FCS settings. Only by preserving and rebuilding human capital can countries durably escape cycles of fragility and underdevelopment.

---

2 Stunting and adult survival are here considered together for easy comparison.
MOST COUNTRIES ACHIEVED HUMAN CAPITAL GAINS IN THE DECADE BEFORE COVID-19

Since this is the first update of the HCI, the 2020 release presents an opportunity to assess the evolution of human capital outcomes as measured by the index over the last decade. The HCI is based on outcomes that typically change slowly from year to year. Some of them—such as stunting and educational test scores—are measured infrequently, every three to five years. As a result, changes in the HCI over a short period are small and may simply reflect updates to some components that are measured sporadically but not others.

To provide more reliable insights on countries’ human capital trajectories over time, this report focuses on changes in the index over the past decade. To this end, a (circa) 2010 version of the HCI is constructed with data carefully curated to maximize comparability with the 2020 results. In particular, only those countries where learning scores were measured by the same international assessment program in 2010 and 2020 enter the comparison. The resulting sample for the 2010 HCI includes 103 countries.

As measured by the HCI, human capital progressed in the vast majority of countries in this sample. On average, between 2010 and 2020, the HCI improved by 2.6 percentage points, about 4 percent of its average value in 2010. One economy in four that experienced a rise in the index recorded gains of more than five percentage points. This means that, in those countries, the productivity of future workers approached the frontier of full productivity by five percentage points – a substantial achievement. Economies starting from lower levels of human capital improved by larger amounts. Better health (child and adult survival and stunting) accounts for about half of the HCI’s changes. Increased enrollments—especially at pre-primary and secondary school levels—account for the bulk of remaining changes. In contrast, progress on learning outcomes has proved difficult, as international test scores failed to keep pace with enrollment gains in many settings.

In the human capital dimensions captured by the index, girls and boys made similar progress over time, with only a handful of countries reporting opposite trends. In the 90 countries where disaggregated data are available and comparisons with 2010 are possible, the average gender ratio is similar in 2010 and 2020, at about 1.06 in favor of girls. Around 2010, the HCI was uniformly larger among girls than among boys, with the exception of seven economies. Among these, the girl-boy ratio improved, approaching or surpassing gender parity, in all but one country over the past decade.

DATA FOR SELECTED COUNTRIES SHOW HOW DISADVANTAGED HOUSEHOLDS SHARED IN HUMAN CAPITAL GAINS

National averages also mask differential trends in human capital between richer and poorer households. Using household data from Demographic and Health Surveys and Multiple Indicator Cluster Surveys, it is possible to calculate a version of the HCI disaggregated by socioeconomic status (SES) for a number of

---

3 As described in chapter 2, this rule is relaxed only for five countries in the sample. These countries are included in the sample with learning scores from different international assessments (TIMMS/PIRLS in 2010 and PISA in 2020). To increase comparability, only scores for secondary schooling are considered for 2010.

4 This sample is, unsurprisingly, skewed toward richer countries where data tend to be more complete and of better quality.

5 With the sample of countries on which the comparison is based skewed towards richer countries, which are closer to the frontier and would naturally have slower change in their human capital, the pace of change is likely underestimated.
low-and middle-income countries. Countries vary substantially in how gains in human-capital outcomes are distributed across the population. For instance, Haiti, Malawi, and Senegal all improved their child survival rates over the last decade. However, the gap between rich and poor households in Haiti remained constant, while it decreased in Malawi and Senegal. Similarly, the years of schooling a child could expect in Burkina Faso, Bangladesh, and India increased significantly. But in Burkina Faso the six-year gap in Expected Years of Schooling (EYS) between rich and poor households has stayed constant over the past 10 years, while in the same period Bangladesh and India—albeit starting from different levels—were able to halve the gap between their richest and poorest households. Côte d’Ivoire’s 25 percentage-point gap between stunting rates for rich and poor households remained unchanged, notwithstanding a significant average reduction in stunting. Conversely, Uganda was able to narrow this gap from a difference of 20 to 16 percentage points between 2000 and 2016. Addressing such rich-poor gaps in human capital must remain a priority for governments committed to equitable growth, not least because the returns to investment in human capital are often highest for disadvantaged groups, especially for measures that act early in life.

Human capital is a central driver of sustainable growth and poverty reduction. However, even for governments that recognize the importance of investing in the human capital of their citizens, the process of designing policy and building institutions that foster human capital accumulation can be complex, with the full benefits taking years and even decades to materialize. This is evidenced in the relatively modest progress measured for the average country on the HCI over the last decade. Adopting a longer timeframe can help identify many forms of government action that can improve human capital. For that purpose, this report incorporates insights from case studies to better understand the trajectories of countries that have made notable improvements in various dimensions of human capital. Sustained political commitment spanning election cycles; coordination across the many programs and agencies that may influence human capital; and using a robust evidence base to inform policy choices emerge as key elements contributing to successful policies for human capital.

SIMULATIONS USING THE HCI QUANTIFY COVID-19’S IMPACTS ON HUMAN CAPITAL

COVID-19 is placing countries’ hard-won human capital gains at risk. A lesson from past pandemics and crises is that their effects are not only felt by those directly impacted, but often ripple across populations and, in many cases, across generations. This underscores the urgent need to protect and rebuild human capital to foster recovery in the short and longer terms.

Setbacks during certain life stages - chiefly early childhood - can have especially damaging and long-lasting effects on human capital accumulation. For example, during childhood, the link between parental income and child health is particularly strong. In previous crises, poorer nutrition and reduced well-being among pregnant mothers led to permanent losses in their children’s cognitive attainment, as

---

6 The analysis of SES-disaggregated HCI outcomes is based on D’Souza, Gatti, and Kraay (2019).
7 It is important to note the dramatic increase in child mortality that occurred in Haiti in 2010 in the aftermath of the country’s catastrophic January 2010 earthquake.
8 This approach informs the work of the World Bank’s Human Capital Project (HCP).
9 See Almond (2006).
well as higher chronic disease rates when the children became adults.10 COVID-19 is likely to produce similar outcomes. In this crisis, human-capital impacts associated with economic shocks come atop reductions in care linked to service disruptions during the pandemic’s acute phase. As such, the current shock to family incomes, even if transitory, may have repercussions for years to come. Children in disadvantaged families will be disproportionately vulnerable to all these effects, thus deepening existing inequalities.

The HCI methodology can be used to quantify some of the potential impacts of COVID-19 on the future human capital of children and youth. For young children—those born during the pandemic or who are currently under the age of five—disruptions to health systems, reduced access to care, and family income losses will materialize as increased child mortality, malnutrition, and stunting. Because stunting and educational outcomes are closely intertwined, the pandemic risks durably setting back children’s learning. According to HCI-based simulations, in low-income countries, young children today can expect their human capital to be about 1 percent lower than it would have been in the absence of COVID-19.

At the height of the pandemic, close to 1.6 billion children worldwide were out of school. For most children who are currently of school age, the pandemic has meant that formal teaching and learning no longer happen face to face. Since the ability to roll out distance learning differ across countries, and even within countries, considerable losses in schooling and learning can be anticipated. The income shocks associated with COVID-19 will also force many children to drop out of school. Putting these effects together suggests that the pandemic could reduce global average learning-adjusted years of school by half a year, from 7.8 to 7.3 years. Translated into the terms of the HCI itself, this loss means a drop of almost 4.5 percent in the HCI of the current cohort of children. For a country with an HCI of 0.5, this signifies a drop of 0.025 HCI points, a reduction of the same order of magnitude as the HCI increase that many countries have achieved over the past decade.

Without a strong policy response now, the pandemic’s negative human-capital effects will likely continue to reduce countries’ productivity and growth prospects for decades. In 20 years, roughly 46 percent of the workforce in a typical country (people aged 20 to 65 years) will be composed of individuals who were either in school or under the age of five during the COVID-19 pandemic. A typical country at that time could still show a loss in itsHCI of almost 1 full HCI point (0.01) due to COVID-19. That is, even if the pandemic turns out to be a temporary shock, the COVID-19 shock could still leave current cohorts of children behind for the rest of their lives. No society can afford to let that happen.

**THIS UPDATE AUGMENTS THE HCI TO REFLECT HOW WELL HUMAN CAPITAL IS USED**

The HCI can be harnessed to track future human-capital losses and guide policies to limit them. The HCI has this capability because it is a metric based on reasonably directly measured markers for key stages of human capital in the growth trajectory of a child. However, the five components of the index do not cover all the important aspects of the accumulation and productive use of human capital. When today’s child becomes a future worker, in many countries she may not be able to find a job, and even if she can,
it might not be a job where she can fully use her skills and cognitive abilities to increase her productivity. In these cases, her human capital can be considered underutilized.

Recognizing the importance of this pattern both for individual people and for policy, this report analyzes two simple extensions of the HCI that adjust the HCI for labor market underutilization of human capital. Both utilization-adjusted human capital indexes (UHCIs) can be calculated for more than 160 countries. Both have the same simple form—the HCI multiplied by a utilization rate—and represent the long-run income gains if a country moves to complete human capital and full utilization of that human capital. The UHCIs are meant to complement, not replace the HCI, given their different purposes.

The two UHCIs take different approaches to measuring utilization. In the basic UHCI, utilization is measured as the fraction of the working-age population that is employed. While this measure is simple and intuitive, it is not able to capture the fact that a large share of employment in developing countries is in jobs where workers may not be able to fully use their human capital to increase their productivity. The full UHCI adjusts for this by introducing the concept of “better employment”—defined as non-agricultural employees, plus employers—which are the types of jobs that are common in high-productivity countries. The full utilization rate depends on the fraction of a country’s working-age population in better employment. Countries with higher HCI scores also face larger utilization penalties if they show low rates of better employment, as they have more human capital to underutilize.

While the different methodologies produce different scores for some individual countries, the basic and full measures yield broadly similar utilization rates across country-income groups and regions, and in general. Utilization rates average around 0.6, but they follow U-shaped curves when plotted against per capita income across countries, being lowest over a wider range of lower-middle-income countries. The analysis of underutilization suggests that moving to a world with complete human capital and complete utilization of that human capital, long-run per capita incomes could almost triple.

Both UHCIs reveal starkly different gender gaps from those calculated using the HCI. While the HCI is roughly equal for boys and girls, with a slight advantage for girls on average, UHCIs are lower for females than males, driven by lower utilization rates. Basic utilization (employment) rates are 20 percentage points lower for women than men in general, and with a gap of more than 40 percentage points in the Middle East and North Africa and South Asia. Female employment rates follow strongly U-shaped curves when plotted against countries’ levels of income, whereas male employment rates are much flatter, and with less dispersion across countries. The gender gap is also present in the full utilization rate, though it is smaller. These results suggest that, while gender gaps in human capital in childhood and adolescence have closed in the last two decades (especially for education), major challenges remain to translate these gains into opportunities for women.

11 Specifically, long run GDP per capita is 1/UHCI times higher in a world with complete human capital and complete utilization than under the status quo. This is a generalization of the interpretation of the HCI. See Pennings (2020) for details.
BETTER MEASUREMENT ENABLES BETTER POLICY

As the COVID-19 crisis continues to unfold, data and measurement are more vital than ever to shape governments’ response in the immediate and guide future policy choices towards (cost-) effective solutions. Better measurement and data use are investments that pay off, a consideration that is particularly important now, as countries face dwindling fiscal space and many competing demands.

By generating a shared understanding among diverse actors, measurement can shine a light on constraints that limit progress in human capital. In the same way, effective measurement can facilitate political consensus based on facts and help muster support for reforms. Measurement also enables policy makers to target support to those who are most in need, which is often where interventions yield the highest payoffs. As policy implementation moves forward, measurement provides feedback to guide course corrections.

In the context of a pandemic, governments that use relevant data in real time are better able to monitor the evolution of disease transmission and continuously update containment strategies, while responding to the immediate and long-term effects of the economic crisis on households and communities. At all times, data are especially important in countries affected by fragility or conflict, though measurement is far more difficult in these settings.

The HCI offers a high-level view of human capital across countries that can help to catalyze new conversations with key stakeholders. At the same time, much greater depth in measurement and research is needed to better understand the dynamics of human capital accumulation, including across socio-economic groups and geography, and how policies can affect it. Some key measurement improvements – such as leveraging phone surveys and making better use of administrative data – can be achieved in the short term. Other improvements will demand a more sustained effort from countries and development partners. These longer-range efforts include rethinking the architecture of country data systems to connect different administrative data sources, and fielding surveys to better understand the needs and behavior of teachers and health providers.

The COVID-19 crisis threatens gains in human capital that countries have achieved through decades of effort. A renewed, society-wide commitment is needed to protect human capital in the immediate and to remediate the looming losses in the longer run. Challenges range from crafting context-sensitive school re-opening protocols to deeper reforms that will promote children’s learning at all stages: starting from cognitive stimulation in the early years, then continuing to nurture relevant skills throughout childhood and adolescence. Building blocks for success will include better-prepared teachers, better-managed schools, and incentives that are aligned across the many stakeholders in education reform.

Support to households will be essential not only to buffer income losses but also to sustain the demand side of schooling and health care. Such support can come through cash transfers, but also interventions aimed at reconnecting workers to jobs. Strengthening disease surveillance and a renewed commitment to universal health coverage will be essential to build resilient health systems that offer affordable, quality care to all. Investments in water, sanitation, and – increasingly – digitalization are important complements to sustain human capital accumulation. Current deepening inequalities in human capital outcomes make it imperative to target interventions to children from the most disadvantaged families. This is the way to prevent setbacks where they risk generating the worst consequences for people’s lifetime trajectories.
With fiscal space shrinking as competing priorities multiply, policymakers face hard choices. Proven strategies include engaging the whole of society, identifying cross-sectoral synergies, and using data to select cost-effective interventions and track their effective implementation. These approaches will not make tough policy trade-offs painless. But they will enable leaders to choose the options that have the highest probability of success. Applying these tools, governments can go far toward protecting and rebuilding human capital in the wake of COVID-19. And that is not all. Strong, evidence-driven human capital investments now can do far more than restore what has been lost. Health, education, social protection, and other policies informed by rigorous measurement can take countries’ human capital beyond the levels previously achieved, opening the way to a more prosperous and inclusive future.
At the organization’s 2018 Annual Meetings, the World Bank Group launched the Human Capital Project, an unprecedented global effort to support human capital development as a core element of countries’ overall strategies to increase productivity and growth. The main objective of the project is rapid progress toward a world in which all children can achieve their full potential. For that to happen, children need to reach school well-nourished and ready to learn, attain real learning in the classroom, and enter the job market as healthy, skilled, and productive adults.

Central to this effort has been the Human Capital Index (HCI), a cross-country metric measuring the human capital that a child born today can expect to attain by her 18th birthday, given the risks of poor health and poor education prevailing in her country.¹ The HCI brings together measures of different dimensions of human capital: health (child survival, stunting, and adult survival rates) and the quantity and quality of schooling (expected years of school and international test scores). Using estimates of the economic returns to education and health, the components are combined into an index that captures the expected productivity of a child born today as a future worker, relative to a benchmark of complete education and full health.

The Human Capital Index ranges from 0 to 1, so that an HCI value of, for instance, 0.5 implies that a child born today will only be half as productive as a future worker as she would be if she enjoyed complete education and full health. By benchmarking shortfalls in future worker productivity deriving from gaps in human capital across countries, the HCI underscores the urgency of improving human capital outcomes for children today.

In response to the call for governments to invest in the human capital of their citizens, 77 countries across the world are now part of the Human Capital Project. These countries have affirmed building, protecting, and employing human capital as a national priority and have been prioritizing investments in human capital and undertaking difficult reforms, sometimes in very challenging contexts. With a view to maintaining this momentum, the 2020 update of the HCI incorporates the most recent data to report HCI scores for 174 countries, adding 17 new countries to the index relative to the 2018 edition.

The update uses new and expanded data for each of the HCI components, with a cut-off date of March 2020. Computed using data collected before COVID-19 had impact on a global scale, the HCI 2020 provides a useful benchmark to track the evolution of human capital and its key components in the wake of the pandemic.

Sections 2 and 3 of this chapter outline the HCI methodology and describe the main features of the HCI 2020 and its components. Section 4 discusses gender differences across countries and regions. Finally, section 5 presents a special spotlight section that considers the unique human capital challenges that arise in states grappling with fragility, conflict, and violence. Section 6 reports the HCI 2020 scores for 174 countries.

¹ The HCI was introduced in World Bank (2018a, 2018d), and the methodology of the HCI is detailed in Kraay (2018).
1.1 THE HUMAN CAPITAL INDEX METHODOLOGY

The HCI is designed to highlight how improvements in current health and education outcomes shape the productivity of the next generation of workers, assuming that children born today experience over the next 18 years the educational opportunities and health risks that children in this age range currently face.

The HCI captures key stages of a child’s trajectory from birth to adulthood. In the poorest countries in the world, there is a significant risk that a child will not survive to her fifth birthday. Even if she does reach school age, there is a further risk that she will not start school, let alone complete the full cycle of 14 years of schooling, from preschool to grade 12, which is the norm in rich countries. The time she does spend in school may translate unevenly into learning, depending on a variety of factors including the quality of teachers and schools that she experiences. When she turns 18, she carries with her the lasting effects of poor health and nutrition during childhood that limit her physical and cognitive abilities as she develop into adulthood.

The design of the HCI has been guided by a number of criteria. First, the HCI is outcome- rather than inputs-based. This helps focus the conversation on what matters—results—and provides incentives for countries not only to invest more, but also to invest better in human capital, without concerns that the HCI might be susceptible to gaming. The likelihood that a cross-country benchmarking exercise can spur policy action is strongly influenced by the over-time and cross-country coverage of the metric. Aiming for good coverage limits the components of the index to data that are systematically available for a large number of countries over time. Yet, for an index to promote change, the components of the HCI should be responsive to policy action in the short to medium term. The need to produce such a metric has oriented the choice of components toward measuring the human capital of the next generation, rather than measuring the stock of human capital of the current workforce, which largely reflects policy choices made decades ago, when the current workforce was of school age.2

As a result, the HCI quantifies the key stages in a child’s human capital trajectory and their consequences for the productivity of the next generation of workers, with three components:

Component 1—Survival from birth to school age, measured using under-5 mortality rates.

Component 2—Expected years of learning-adjusted school, combining information on the quantity and quality of education. The quantity of education is measured as the number of years of school a child can expect to obtain by age 18 given the prevailing pattern of enrollment rates across grades. The quality of education reflects work undertaken at the World Bank to harmonize test scores from major international student achievement testing programs (Patrinos and Angrist, 2018). These are combined into a measure of learning-adjusted school years as proposed in the 2018 World Development Report (see Box 1.1).

Component 3—Health. In the absence of a single broadly-accepted, directly measured, and widely available metric, the overall health environment is captured by two proxies: (a) adult survival rates, defined as the fraction of 15-year-olds who survive until age 60, and (b) the rate of stunting for children under age 5. Adult survival rates can be interpreted as a proxy for the range of fatal and nonfatal health outcomes that a child born today would experience as an adult if current conditions prevail into the future. Stunting is broadly accepted as a proxy for the prenatal, infant, and early childhood health environment, and so summarizes the risks to good

---

2 As a result of the criteria for its construction, the index measures dimensions of human capital that are important, but not all of the important dimensions of human capital are included in the index.
health that children born today are likely to experience in their early years—with important consequences for health and well-being in adulthood.

The health and education components of human capital have intrinsic value that is undeniably important but difficult to quantify. This in turn makes it challenging to combine the different components into a single index. Rather than relying on ad hoc aggregation with arbitrary weights, the HCI uses the estimated earnings associated with an additional unit of health and education to translate them into contributions to worker productivity, relative to a benchmark of complete Box 1.1: Learning-Adjusted Years of Schooling

The knowledge and skills that an individual acquires through schooling form an important part of her human capital. However, the standard summary measure for education used in aggregate-level contexts—the average number of years of schooling in a population—is an imprecise proxy for education, because a given number of years in school leads to much more learning in some settings than in others. As recent research shows, students in different countries who have completed the same number of years of school often have vastly different learning outcomes.

The Learning-Adjusted Years of Schooling (LAYS), a measure described in Filmer et al. (2018), addresses this concern by combining information on the quantity and quality of schooling into a single easy-to-understand metric of progress. It is calculated as the product of average years of school and a particular measure of learning relative to a numeraire:

\[ \text{LAYS}_c = S_c \times R^n_c \]  

where \( S_c \) is a measure of the average years of schooling acquired by a relevant cohort of the population of country \( c \), and \( R^n_c \) is a measure of learning for a relevant cohort of students in country \( c \), relative to a numeraire (or benchmark). For the HCI, Expected Years of School measures the quantity of education. Harmonized Test Scores from the 2020 update of the Global Dataset on Education Quality provides information on education quality relative to a benchmark score of 625, which corresponds to the Trends in International Mathematics and Science Study (TIMSS) standard of advanced achievement:

\[ \text{LAYS}_c = \text{EYS}_c \times \frac{\text{HTS}_{c_625}}{625} \]

By adjusting years of school for quality, LAYS reflects the reality that children in some countries learn far less than those in other countries, despite being in school for a similar amount of time. The simplicity and transparency of its construction make LAYS a compelling summary measure of education to use in policy dialogue. Filmer et al. (2018) also find that LAYS improves upon the standard metric of average years of schooling as a predictor of economic growth.

Source: Filmer et al. (2018).

a In Nigeria, for example, 19 percent of young adults who have completed only primary education are able to read; by contrast, 80 percent of Tanzanians in the same category are literate (Kaffenberger and Pritchett 2017, as reproduced in World Bank 2018).

b Like all aggregate measures, LAYS should be used with caution. Because there are standard errors around test measures, any LAYS measure will also have some error band around it. This means that it is important not to overinterpret small cross-country differences or small changes over time.
education and full health (see Box 1.2). The resulting index ranges between 0 and 1. A country in which a child born today can expect to achieve full health (no stunting and 100 percent adult survival) and full education potential (14 years of high-quality school by age 18) would score a value of 1. Therefore, a score of 0.70 indicates that the productivity as a future worker of a child born today is 30 percent below what could have been achieved with complete education and full health. Because the theoretical underpinnings of the HCI are in the development accounting literature, the index is linked to real differences in how much income a country can generate in the long run (see Box 1.3 for limitations of the HCI). If a country has a score of 0.50, then the gross domestic product (GDP) per worker could be twice as high if the country reached the benchmark of complete education and full health (see appendix A for a detailed discussion of the HCI methodology).

### 1.2 THE HUMAN CAPITAL INDEX 2020

The HCI 2020 is reported later in Table 1.2. Country scores are sorted from lowest to highest. Next to the HCI score, lower and upper bounds for the estimates are reported. Unlike the HCI 2018 launch, countries’ rankings are not reported, for reasons that are detailed in Box 1.6.

The sobering reality is that, as measured by the Human Capital Index 2020, worldwide, a child born today would expect to achieve on average only 56 percent of her full productivity as a future worker. This is before accounting for any impact that may have resulted from the COVID-19 pandemic. Clearly there is considerable heterogeneity around the 56 percent figure. Importantly, the HCI is lower in poor countries than in rich countries by a substantial margin. In the poorest countries in the world, a child born today will grow up to...
Box 1.2: The HCI’s aggregation methodology

The components of the HCI are combined into a single index by first converting them into contributions to productivity relative to a benchmark of complete education and full health. Multiplying these contributions to productivity together gives the overall HCI:

\[ HCI = \text{Survival} \times \text{School} \times \text{Health} \]  

In the case of survival, the relative productivity interpretation is stark: children who do not survive childhood never become productive adults. As a result, expected productivity as a future worker of a child born today is reduced by a factor equal to the survival rate, relative to the benchmark where all children survive.

\[ \text{Survival} = \frac{1}{1 - \text{Under-5 Mortality Rate}} \]  

The benchmark of complete high-quality education corresponds to 14 years of school and a harmonized test score of 625. The relative productivity interpretation for education is anchored in the large empirical literature measuring the returns to education at the individual level. A rough consensus from this literature is that an additional year of school raises earnings by about 8 percent. The parameter \( \phi = 0.08 \) measures the returns to an additional year of school and is used to convert differences in learning-adjusted years of school across countries into differences in worker productivity.

\[ \text{School} = e^{\phi \left( \frac{\text{Expected Years of School} \times \text{Harmonized Test Score}}{625} - 14 \right)} \]  

Compared with a benchmark where all children obtain a full 14 years of school by age 18, a child who obtains only 10 years of education can expect to be 32 percent less productive as an adult (a gap of 4 years of education, multiplied by 8 percent per year).

In the case of health, the relative productivity interpretation is based on the empirical literature measuring the economic returns to better health at the individual level. The key challenge in this literature is that there is no unique, directly measured summary indicator of the various aspects of health that matter for productivity. This microeconometric literature often uses proxy indicators for health, such as adult height. This is because adult height can be measured directly and reflects the accumulation of shocks to health through childhood and adolescence. A rough consensus drawn from this literature is that an improvement in health associated with a one-centimeter increase in adult height raises productivity by 3.4 percent.

Converting this evidence on the returns to one proxy for health (adult height) into the other proxies for health used in the HCI (stunting and adult survival) requires information on the relationships between these different proxies:

- For stunting, there is a direct relationship between stunting in childhood and future adult height, because growth deficits in childhood persist to a large extent into adulthood, together with the associated health and cognitive deficits. Available evidence suggests that a reduction in stunting rates of 10 percentage points increases attained adult height by approximately one centimeter \((0.1 \times 10.2)\), which increases productivity by 3.5 percent.

- For adult survival, the empirical evidence suggests that, if overall health improves, both adult height and adult survival rates increase in such a way that adult height rises by 1.9 centimeters for every 10-percentage-point improvement in adult survival. This implies that an
improvement in health that leads to an increase in adult survival rates of 10 percentage points is associated with an improvement in worker productivity of $1.9 \times 3.4\%$, or 6.5 percent.

In the HCI, the estimated contributions of health to worker productivity based on these two alternative proxies are averaged together, if both are available, and are used individually if only one of the two is available. The contribution of health to productivity is expressed relative to the benchmark of full health, defined as the absence of stunting, and a 100 percent adult survival rate. For example, compared with a benchmark of no stunting, in a country where the stunting rate is 30 percent, poor health reduces worker productivity by $30 \times 0.34\%$ or 10 percent.

$$\text{Health} = e^{(\phi \times (\text{Adult Survival Rate} - 1) + \gamma_{\text{Stunting}} \times (\text{Not Stunted Rate} - 1))/2}$$ (4)

Compared with the benchmark of 100 percent adult survival, poor health reduces worker productivity by $(30 \times 0.65)\%$, or 19.5 percent, in a country where the adult survival rate is 70 percent. The average of the two estimates of the effect of health on productivity is used in the HCI.

These parameters used to convert the components of the index into their contributions to productivity ($\phi = 0.08$ for school, $\gamma_{\text{ASR}} = 0.65$ for adult survival, and $\gamma_{\text{Stunting}} = 0.35$ for stunting) serve as weights in the construction of the HCI. The weights are chosen to be the same across countries, so that cross-country differences in the HCI reflect only cross-country differences in the component variables. This facilitates the interpretation of the index. This is also a pragmatic choice, because estimating country-specific returns to education and health for all countries included in the HCI is not feasible.

be only 30 percent as productive as she could be, while in the richest countries the corresponding figure is 80 percent or more (see Figure 1.1, which plots the HCI 2020 on the vertical axis against log GDP per capita at PPP on the horizontal axis).

While the correlation between the HCI and GDP per capita is high, some economies perform significantly better than their income levels might suggest. These include Estonia, Kyrgyz Republic, Vietnam, and West Bank and Gaza. Conversely, in a number of countries, human capital is lower than per capita income would suggest. Among these are a few resource-rich countries, where human capital has not yet matched the potential that one would envisage given these countries’ development. A child in Sub-Saharan Africa can expect to be only 58 percent as productive as a future worker as a child in Europe and Central Asia (see Table 1.1).

The correlation between poverty and low HCI scores is also high. Given that better education and health translate to improved productivity for people, and that human capital is often the only asset the poor have, the World Bank’s twin goals of shared prosperity and eradicating extreme poverty are unlikely to be met without human capital improvements. Accordingly, the world’s extreme poor are disproportionately found in countries with the lowest HCI; 30 percent of the world’s poor reside in the 10 countries with the lowest HCI values, although these 10 countries are home to only 5 percent of the total global population (Figure 1.2).
Figure 1.1: The Human Capital Index 2020

Source: World Bank calculations based on the 2020 update of the Human Capital Index for HCI data and the World Development Indicators and Penn World Tables 9.1 for per capita GDP data.

Notes: The figure uses real GDP per capita at PPP, in constant 2011 US$, for most recently available data as of 2019. Per capita GDP data for South Sudan are not available. The figure plots the country-level HCI on the y-axis and GDP per capita in PPP on the x-axis. The dashed line illustrates the fitted regression line between GDP per capita and the HCI 2020. Scatter points above (below) the fitted regression line illustrate economies that perform higher (lower) in the HCI than their level of GDP would predict. Countries above the 95th and below the 5th percentile in distance to the regression fitted line are labeled.

Figure 1.2: Concentration of the extreme poor in economies sorted by their Human Capital Index

Source: World Bank calculations based on the 2020 update of the Human Capital Index. Poverty values come from Corral et al. (2020) and are calculated pre-COVID-19.

Notes: The figure corresponds to the 174 economies for which a Human Capital Index has been calculated. It covers roughly 98 percent of the world’s population. Economies are sorted by their HCI value. The horizontal axis represents the share of the global population accounted for by the countries once sorted.

b. Expected Years of School

c. Harmonized Test Scores

d. Fraction of Children Under 5 Not Stunted

e. Adult Survival Rate

Notes: Each box spans the interquartile range with the upper and lower end of the boxes illustrating the 25th and 75th percentile values. The horizontal lines in the inner boxes represent the median value. Outer horizontal lines show maximum and minimum values excluding outliers. Thinner box plots indicate less dispersion in values.
In fact, 80 percent of the world’s extreme poor reside in countries with an HCI under 0.5. If prosperity is to be shared, growth must be inclusive for those at the bottom of the distribution, and inclusive growth necessitates strong investments in human capital.

Two elements help explain how different dimensions of human capital contribute to overall cross-country differences in the HCI. The first are the weights of the health and education components of the HCI, reflecting the empirical literature on the contribution of health and education to earnings (Box 1.2 and appendix A). Second, the components have different distributions, globally and by country income groupings, according to the World Bank most recent classification. For example, the variation of child survival is nine times larger among low-income than among high-income countries, where child survival is uniformly close to 100 percent (Figure 1.3).

A simple decomposition exercise can help account for differences in the HCI across country income groups. Consider the HCI difference between the typical low-income and high-income country, which is about 0.33 (Figure 1.4). Of these 33 HCI points, almost 25 are accounted for by the differences in expected years of school and harmonized test scores. Overall, differences in the quality and quantity of schooling account for the largest share of index differences across country income groups, ranging from 65 to 85 percent.

There is also considerable heterogeneity within country income groups, and the difference in HCI between the country with the lowest and the country with the highest HCI in each income group rivals the differences between income groups and, in some cases, exceeds it. For example, the difference in the HCI between the top and bottom performers among high-income economies is roughly 0.38, or 38 HCI points. This compares with a difference of 33 points between the average HCI values of high- and low-income countries. Overall, both within and across all groups, education still accounts for the largest share of the differences observed between top and bottom performers (Figure 1.5). However, education accounts for a smaller share as one moves down income groups, falling from roughly 90 percent among high-income to 60 percent among low-income economies. In contrast, differences in child survival rates account for less of the difference in HCI scores among high-income

---

4 The decomposition of the group averages is obtained via a Shapley decomposition. For an application see Azevedo, Inchauste, and Sanfelice 2013.
countries, largely because countries in this group are close to universal child survival. The same is true for the health component, with stunting and adult survival taken together for easy comparison. Health differences explain a lower share of HCl differences as one moves from low- to higher-income countries, since health outcomes tend to be uniformly better as countries get richer. These results reflect the fact that, within high-income groups, values for health and survival components in most countries are close to the frontier, whereas there is still considerable variation in test scores across countries.

Gaps in human capital outcomes between rich and poor people within countries can be quite large. A socio-economic disaggregation of the HCI, constructed using comparable survey data for 50 low- and middle-income countries, revealed that differences across socioeconomic quintiles within countries account for nearly one-third of the total variation in human capital. Outcomes can also vary across rural-urban status, as in the case of Romania. In some of the country’s counties, there are urban areas with learning outcomes as high as top performers in Europe, while some rural areas rank at par with countries in the bottom third of the HCI distribution. Some of these within-country differences align with ethnic divides. For example, in Vietnam, survey data from 2014 disaggregated by ethnic group show that ethnic minorities have an HCI score of 0.62, compared with 0.75 for the ethnic-majority Kinh. At 32 percent, stunting rates are two times larger among ethnic minorities than among the Kinh majority. School enrollment also lags among ethnic minorities relative to their Kinh peers by 30 percentage points.

---

5 Among upper-middle-income economies, the health component value of the bottom performer is higher than that of the top performer, and thus it accounts for a negative share of the difference.

1.3 HCI 2020 UPDATE—INDEX COMPONENTS

1.3.1 HCI components and data sources

The components of the Human Capital Index are built using publicly available official data, primarily from administrative sources. The data are subject to a careful vetting process with World Bank country teams and, at the discretion of country teams, with line ministry counterparts. These data and the relevant definitions are described below and in more detail in appendix C.

Box 1.3: Limitations of the HCI

Like all cross-country benchmarking exercises, the HCI has limitations. Components of the HCI such as stunting and test scores are measured only infrequently in some countries and not at all in others. Data on test scores come from different international testing programs that need to be converted into common units, and the age of test-takers and the subjects covered vary across testing programs. Moreover, test scores may not accurately reflect the quality of the whole education system in a country, to the extent that test-takers are not representative of the population of all students. Reliable measures of the quality of tertiary education that are comparable across most countries of the world do not yet exist, despite the importance of higher education for human capital in a rapidly changing world. The data on enrollment rates needed to estimate expected years of school often have many gaps and are reported with significant lags. Socioemotional skills are not explicitly captured. Child and adult survival rates are imprecisely estimated in countries where vital registries are incomplete or nonexistent. These limitations have implications not only for the construction of the 2020 update but also for the comparison of the index over time.

One objective of the HCI is to call attention to these data shortcomings and to galvanize action to remedy them. Improving data will take time. In the interim and in recognition of these limitations, the HCI should be interpreted with caution. The HCI provides rough estimates of how current education and health will shape the productivity of future workers but is not a finely graduated measurement that can distinguish small differences between countries. Naturally, because the HCI captures outcomes, it is not a checklist of policy actions, and the proper type and scale of interventions to build human capital will be different in different countries. Although the HCI combines education and health into a single measure, it is too blunt a tool to inform the cost-effectiveness of policy interventions in these areas, which should instead be assessed based on careful cost-benefit analysis and impact assessments of specific programs. Because the HCI uses common estimates of the economic returns to health and education for all countries, it does not capture cross-country differences in how well countries are able to productively deploy the human capital they have. Finally, the HCI is not a measure of welfare, nor is it a summary of the intrinsic values of health and education; rather, it is simply a measure of the contribution of current health and education outcomes to the productivity of future workers.

Child survival

The probability of survival to age 5 is calculated as the complement of the under-5 mortality rate. The under-5 mortality rate is the probability of a child born in a specified year dying before reaching the age of 5 if subject to current age-specific mortality rates. It is frequently expressed as a rate per 1,000 live births, in which case it must be divided by 1,000 to obtain the probability of dying before age 5. Under-5 mortality rates are calculated by the United Nations Interagency
Group for Child Mortality Estimation (IGME) based on mortality as recorded in household surveys and vital registries. For the 2020 update of the HCI, under-5 mortality rates come from the September 2019 update of the IGME estimates and are available at the Child Mortality Estimates website.\textsuperscript{10}

**Expected years of school**

The expected years of school (EYS) component of the HCI captures the number of years of school a child born today can expect to obtain by age 18, given the prevailing pattern of enrollment rates in her country. Conceptually, EYS is the sum of enrollment rates by age from ages 4 to 17. Because age-specific enrollment rates are neither broadly nor systematically available, data on enrollment rates by level of school are used to approximate enrollment rates in different age brackets. Pre-primary enrollment rates approximate the enrollment rates for 4- and 5-year-olds, primary enrollment rates approximate the rates for 6- to 11-year-olds, lower-secondary rates approximate for 12- to 14-year-olds, and upper secondary rates approximate for 15- to 17-year-olds. Cross-country definitions in school starting ages and the duration of the various levels of school imply that these will only be approximations of the number of years of school a child can expect to complete by age 18. Enrollment rates for 2020 for each school level and for different enrollment rate types are obtained from the UNESCO Institute for Statistics (UIS).\textsuperscript{11} UIS data were then complemented with inputs from World Bank teams working on specific countries to validate the data and provide more recent values when available.\textsuperscript{12}

**Harmonized test scores**

The school quality indicator is based on a large-scale effort to harmonize international student achievement tests from several multicountry testing programs to produce the Global Dataset on Education Quality. A detailed description of the test score harmonization exercise is provided in Patrinos and Angrist (2018), and the HCI draws on an updated version of this dataset as of January 2020. The dataset harmonizes scores from three major international testing programs: the Trends in International Mathematics and Science Study (TIMSS), the Progress in International Reading Literacy Study (PIRLS), and the Programme for International Student Assessment (PISA). It further includes four major regional testing programs: the Southern and Eastern Africa Consortium for Monitoring Educational Quality (SACMEQ), the Program for the Analysis of Education Systems (PASEC), the Latin American Laboratory for Assessment of the Quality of Education (LLECE), and the Pacific Island Learning and Numeracy Assessment (PILNA). It also incorporates Early Grade Reading Assessments (EGRAs) coordinated by the United States Agency for International Development. The 2020 update of the Global Dataset on Education Quality extends the database to 184 countries and economies from 2000 to 2019, drawing on a large-scale effort by the World Bank to collect learning data globally. Updates to the database come from new data from PISA 2018, PISA for Development (PISA-D), PILNA, and EGRA. The database adds 20 new countries.\textsuperscript{14} This brings the percentage of the global school-age population represented by the database to 98.7 percent. In addition, more recent data points have been added for 94 countries (Angrist, \textsuperscript{13}PISA-D results are only used for Panama and Bhutan.\textsuperscript{14} For the 20 new countries included in the Global Dataset on Education Quality, eight are updated using EGRAs, eight using PILNA, three using PISA and PISA-D, and one using a national TIMSS-equivalent assessment.)
Iqbal, and Patrinos, 2020).\textsuperscript{15} Since the launch of the HCI in 2018, a complementary measure has been created to address foundational skills and to help countries prioritize their response to HCI and LAYS scores: Learning Poverty, the share of 10-year-olds who cannot read and understand a simple story (see Box 1.4). The correlation between Learning Poverty and LAYS is very high, in the range of \(-0.90\). The Learning Poverty measure is available for 113 of the economies with an HCI 2020.

**Fraction of children under 5 not stunted**

The fraction of children under 5 not stunted is calculated as the complement of the under-5 stunting rate. The stunting rate is defined as the share of children under the age of 5 whose height is more than two reference standard deviations below the reference median for their ages. The reference median and standard deviations are set by the World Health Organization (WHO) for normal healthy child development.\textsuperscript{16} Child-level stunting prevalence is averaged across the relevant 0–5 age range to arrive at an overall under-5 stunting rate. The stunting rate is used as a proxy for latent health of the population, in addition to the adult survival rate, in countries where stunting data are available, as discussed below. Stunting rates for the 2020 update of the HCI come from the March 2020 update of the Joint Malnutrition Estimates (JME) database, available at the UNICEF website.\textsuperscript{17} This latest update to the database allows an update of stunting rates for 54 countries, and adds stunting rates for Argentina, Bulgaria, and Uzbekistan, which did not have a rate in the previous iteration of the HCI.

**Adult survival rates**

The adult survival rate is calculated as the complement of the mortality rate for 15- to 60-year-olds. The mortality rate for 15- to 60-year-olds is the probability of a 15-year-old in a specified year dying before reaching the age of 60 if subject to current age-specific mortality rates. It is frequently expressed as a rate per 1,000 alive at 15, in which case it must be divided by 1,000 to obtain the probability of a 15-year-old dying before age 60. Adult mortality rates for the 2020 update of the HCI come from the 2019 update of the UNPD World Population Prospects estimates, available at the World Population Prospects website.\textsuperscript{18} Since UNPD does not individually report adult mortality rates for countries with less than 90,000 inhabitants, data from the UNPD are supplemented with adult mortality rates from the Global Burden of Disease (GBD) project, managed by the Institute of Health Metrics and Evaluation (IHME). Data from this source are used for Dominica and The Republic of the Marshall Islands. Data for Nauru, Palau, San Marino, St. Kitts and Nevis, and Tuvalu come from the World Health Organization (WHO). The GBD data for the HCI 2020 come from the GBD 2017 update and can be retrieved from the IHME data visualization site.\textsuperscript{19} The WHO data are located on the UN Data platform.\textsuperscript{20}

### 1.3.2 Index components across countries

All five components of the index increase with income, though at a different pace (Figure 1.6). Child survival rates range from 0.998 (2 deaths per 1,000 live births) in the richest countries to around 0.880 (120 deaths per 1,000 live births) in the poorest countries, reflecting the disproportionate burden of child mortality that low-income countries

---

\textsuperscript{15} Of the 94 countries with updated test scores in the Global Dataset on Education Quality, seventy-five are from PISA 2018, seven from PISA-D, five from EGRAs, and seven from PILNA.

\textsuperscript{16} World Health Organization (2009).

Box 1.4: Measuring Learning Poverty

The World Bank collaborated with the UNESCO Institute for Statistics (UIS) to create a measure of Learning Poverty—the share of 10-year-olds who cannot read and understand a simple story.

Using a database developed jointly with UIS, the Bank estimates that 53 percent of children in low- and middle-income countries suffer from learning poverty. In the poorest countries, the number is often more than 80 percent. Such high levels of learning poverty are an early warning sign that the LAYS indicator, which measures quantity and quality of education that 18-year-olds have benefited from, will be unacceptably low for that cohort of children in a few years. In higher-performing systems, virtually all children learn to read with comprehension by age 10. While it may take decades to build up the high-quality education systems that lead to the highest scores on the LAYS indicator of the HCI, teaching children to reach a minimum proficiency in reading requires much less time.

Why reading? Children need to learn to read so that they can read to learn. Those who do not become proficient in reading by the end of primary school often cannot catch up later, because the curriculum of every school system assumes that secondary-school students can learn through reading. Reading is, in other words, a gateway to all types of academic learning. This is not to say that reading is the only skill that matters. Reading proficiency can serve as a proxy or warning indicator for foundational learning in other areas that are also essential, like mathematics and reasoning abilities. Education systems that enable all children to read are likely to succeed in helping them learn other subjects as well. Across countries and schools, the data show that proficiency rates in reading are highly correlated with proficiency in other subjects.

How is learning poverty calculated? Conceptually similar to the LAYS indicator in the HCI for youth, the Learning Poverty measure combines learning with enrollment, to emphasize the importance of learning for all children and not just those currently in school. The learning component captures enrolled students who cannot read with comprehension, while the participation component corresponds to the out-of-school rate. “Reading with comprehension” is defined here as reaching the global minimum proficiency in literacy. The UIS leads the Global Alliance to Monitor Learning (GAML), which agreed to a common definition of minimum proficiency in literacy for the purposes of monitoring Sustainable Development Goal (SDG) 4. With this definition, several cross-national and some national assessments were harmonized by applying GAML’s definition of reading proficiency as a common benchmark. Unlike the HCI, Learning Poverty relies only on assessments targeting children from grades 4 to 6. For each assessment incorporated into the database, the harmonization process looks at the definitions of each level of proficiency for that exam and selects the one that maps most clearly to the GAML definition. The harmonization process allowed much greater coverage of countries than relying on a single assessment like the Progress in International Reading Literacy Study (PIRLS)—an excellent assessment for measuring Learning Poverty, but one in which relatively few low- and middle-income countries participate. The high correlation between students’ performance on different assessments increased confidence that this harmonization method is valid. Once the share of children below minimum proficiency is calculated, the final step in calculating Learning Poverty is to adjust this share for out-of-school children of primary-school age who are considered nonproficient in reading.

The HCI, LAYS, and Learning Poverty, each with its own unique mandate and methodology, are synthetic indicators intended to build political commitment and galvanize action.

Figure 1.6: Human Capital Index 2020—index components

Notes: The figure reports the most recent cross-section of 174 economies for the five HCI components (child survival, expected years of school, harmonized test scores, fraction of children under 5 not stunted, and adult survival), as used to calculate the 2020 HCI. Each panel plots the country-level averages for each component on the y-axis and GDP per capita in PPP on the x-axis. The dashed line illustrates the fitted regression line between GDP per capita and the respective component. Scatter points above (below) the fitted regression line illustrate economies that perform higher (lower) in the outcome variable than their level of GDP would predict. Countries above the 95th and below the 5th percentile in distance to the fitted regression line are labeled.
continue to face. Child survival rates also vary significantly by region, with economies in the Europe and Central Asia region bundled at the top of the distribution and the lowest rates in Sub-Saharan Africa, in countries like Chad, Nigeria, and Sierra Leone. However, in a number of economies in Sub-Saharan Africa, including Burundi, Malawi, or Rwanda, child survival rates are significantly higher than their level of GDP would predict (Figure 1.6).

While internationally comparable stunting measures are primarily collected in low- and middle-income countries, the share of stunted children decreases as countries get richer. However, income and stunting rates do not always go in lockstep, including across socioeconomic groups within countries. For example, in countries such as Burundi, Niger, and Tanzania, the gap in stunting rates between the 1st and the 4th socioeconomic quintiles is smaller than the gap between stunting rates in the 4th and 5th quintiles (the richest households), reflecting the interaction of environmental, economic, and cultural factors that can contribute to slower physical development in children. In countries such as Papua New Guinea, Timor-Leste, and Guatemala, more than 45 percent of children are stunted. On the other end of the spectrum are economies like Samoa, Tonga, Moldova, or West Bank and Gaza, where the stunting rate is below 10 percent, and significantly lower than their level of GDP would predict. The second proxy for health—adult survival—is lowest in Lesotho, Eswatini, and the Central African Republic, where the chances of surviving from age 15 to age 60 are at 60 percent or lower.

Quantity of schooling—as measured by Expected Years of School (EYS)—increases as countries get richer. High-income countries are bundled at the top of the distribution and low-income countries are at the bottom of the distribution. However, in economies like Malawi, Zimbabwe, Nepal, or the Kyrgyz Republic, expected years of school are higher than their level of GDP would predict, reflecting the progress these countries were able to make in improving access to schooling (Figure 1.6).

Outliers where the quantity of schooling is about 2.5 to 5.3 years below what their level of GDP would predict include economies such as Iraq, Mali, and Liberia, which are characterized by different levels of institutional fragility and conflict. Quality of schooling—as measured by harmonized test scores (HTS)—increases with income, too, though seemingly faster than years of education. The HTS ranges from a score of around 305 in the poorest countries to a score of around 575 in the richest countries (Figure 1.6). To interpret the units of the HTS, note that 400 corresponds to the benchmark of “low proficiency” in TIMSS at the student level, while 625 corresponds to “advanced proficiency.” Accounting for the level of GDP, economies such as Vietnam, Ukraine, and Uzbekistan, as well as Kenya and Cambodia, performed particularly well in learning. Vietnam reaches an HTS of 519, a level similar to countries like Sweden, the Netherlands, and New Zealand, which are significantly richer. Economies where learning is below what their income per capita would predict include high-income countries such as Kuwait, Saudi Arabia, and Qatar. Their relatively disappointing performance in learning may result in part from a traditional emphasis on investing in school infrastructure rather than other factors that are also necessary to improve educational outcomes. These include governance and accountability, effective monitoring mechanisms, information sharing with parents and students, and school systems geared

---

21 de Onis and Branca (2016).
22 World Bank (2019b).
23 Note that Vietnam enters the HCI 2020 with its 2015 PISA score, since 2018 PISA scores are not reported for the country. While Vietnam participated in the 2018 round of PISA using paper-based instruments, the OECD’s country note states that the international comparability of the country’s performance in reading, mathematics, and science could not be fully ensured (OECD 2019).
toward inclusive learning. Education systems in these countries may also be reacting to the pull from labor markets, where pervasive informality generates low returns to schooling, and the lure of public employment puts more emphasis on diplomas than on skills. As a consequence, learning lags behind the progress that countries in this region have achieved in access to schooling and gender parity.

### 1.4 HCI MEASURES OF GENDER GAPS IN HUMAN CAPITAL

Globally, the average HCI for girls is slightly higher (0.59) than that for boys (0.56). This pattern can be observed across all HCI components (Figure 1.7).

While the gap between boys and girls has closed in these early-life outcomes, boys and girls both remain far from the frontier of complete education and full health. The gap in human capital compared to full potential far exceeds any gender gap in HCI in most countries. Boys and girls are 2.6 and 2.5 years of schooling away from completing upper-secondary education. A large share of boys and girls are stunted, 24 and 21 percent, respectively. Far too many boys and girls do not survive beyond their fifth birthday, 2.8 and 2.4 percent, respectively. Conditional on making it to age 15, only 83 percent of boys and 89 percent of girls are expected to survive to age 60.

The global HCI average, however, masks important regional and income-group differences with respect to gender (Figure 1.8). While girls still surpass boys in the HCI value overall, with lower stunting as well as lower child and adult mortality rates in all regions and income groups, advantages for girls are more prominent in some regions and muted in others. For example, the gap in stunting rates between girls and boys is as high as 4.6 percentage points in Sub-Saharan Africa, with boys having a higher stunting rate.

---

24 Galal et al. (2008).
26 This difference is statistically significant at the 5 percent level.
With regard to expected years of school, girls are still disadvantaged compared to boys in South Asia and Sub-Saharan Africa, where girls and boys experience 0.45 and 0.15 years of school disadvantage, respectively (Figure 1.8). In settings affected by fragility, conflict, and violence, girls on average complete 0.14 years less schooling than boys. In low-income countries, aside from completing less schooling, girls also have lower harmonized test scores, with a 0.8 percent deficit.

The gender gap in the Human Capital Index varies quite widely across countries, with a difference in the score between boys and girls ranging from a low of -0.043 in Afghanistan to a high of 0.096 in Lithuania (Figure 1.9). Overall, girls are outperforming boys in 140 of the 153 countries for which sex-disaggregated data are available.

Expected years of school and harmonized test scores show similar patterns. The gender gap in expected years of school favors boys in 46 countries...
**Figure 1.9: Country-level variations in gender gaps in HCI and education components**

Notes: The X-axis show countries ranked by girl-boy gap in the variable in question.
(30 percent of all countries with a sex-disaggregated HCI, Figure 1.9). In learning outcomes, boys are favored in 31 countries (20 percent). Although expected years of school are higher for girls than for boys in most countries, in those countries where boys have an advantage over girls with respect to schooling, the magnitude of the resulting gender disparity is larger. For example, in Tunisia, Kiribati, and St. Vincent and the Grenadines, girls on average complete more than one extra year of school compared to boys, while in Angola and Afghanistan, boys on average complete 2.3 to 2.7 more years of school than girls. The top five countries where girls outperform boys in learning outcomes are Nauru, Qatar, Oman, Bahrain, and Samoa, three of which are in the Middle East and North Africa region. Conversely, 6 in 10 countries where boys have higher learning outcomes than girls are in Sub-Saharan Africa. In high- and middle-income countries, girls outperform boys in enrollment and learning outcomes. For example, in Guyana, girls are expected to complete one-fifth of a year more schooling than boys with 5 percent higher learning outcomes. This reverse gap in enrollment begins in lower-secondary education and widens in upper-secondary, where girls are 11 percent more likely to be enrolled than boys.

Overall, out of the 13 countries where boys have a higher HCI score than girls, eight are in Sub-Saharan Africa, two in South Asia, one in the East Asia and Pacific region, one in Latin America and the Caribbean, and one in the Middle East and North Africa region. Seven countries are low-income countries, five are lower-middle-income countries, and one is an upper-middle-income country. In all 13 countries, expected years of school for boys are higher than for girls, ranging from a quarter year in Peru to almost three full years in Afghanistan. On average, boys have a 10-percentage-point higher likelihood of completing primary education, a 12-percentage-point higher likelihood of completing lower-secondary education, and a 13-percentage-point higher likelihood of completing upper-secondary education. Boys also have better learning outcomes than girls in nine of these 13 countries. In Chad and Guinea, this difference reaches more than 14 percent in favor of boys.

Human capital accumulation is a complex process. This is especially clear when looking at the HCI to understand gender gaps. Women, girls, men, and boys face different challenges at different stages of the life cycle. The HCI focuses on specific life-cycle stages in which girls have slight biological advantages over boys in child and adult survival rates. As with any indicator, the components of the index are not perfect proxies of human capital and try to balance accuracy and data availability. For example, the index does not capture gender bias in terms of sex-selective abortions (what might be called prebirth survival). Moreover, health is proxied by adult mortality rates, but some evidence shows that, while women live longer than men, they are not necessarily in better health.

---

28 Stunting rates are calculated using survey data and differences in average rates between girls and boys may not be statistically significant.
29 United Nations (2011) and Crimmins et al. (2019).
30 The number of “missing women” was estimated to be 126 million in 2010 (Bongaarts and Guilmoto 2015). This refers to the deficit of females relative to males, compared to the figures that would have been observed had all female fetuses been allowed to be born.
31 Guerra et al. (2008); Bora and Saikia (2018).
a measure of the human capital potential of children today, the index does not capture gender gaps in human capital among the current population of adults. These caveats are important backdrops to any analysis of gender gaps using the HCI. Finally, the index implicitly assumes that a child born today will be absorbed into the labor market to use her human capital potential in terms of income generation, when, in fact, female labor participation rates, globally, are 27 percentage points lower than male labor participation rates. Chapter 4 on human capital utilization delves into this, by proposing an adjustment of the HCI that captures labor outcomes. These outcomes reflect one of many ways human capital is utilized to improve well-being and overall economic development.

Equal access to education and health is far from realized. Despite progress, girls continue to face greater challenges. Child marriage, household responsibilities, teenage pregnancies, and gender-based violence in schools pose challenges in keeping girls enrolled, especially, but not only, in low-income settings.

1.5 HUMAN CAPITAL IN FRAGILE AND CONFLICT-AFFECTED CONTEXTS

Human capital accumulation requires a sustained political commitment, an adequate and timely resource mobilization, a whole-of-society approach, and effective use of data and measurement. However, these features are not typical of economies that are grappling with fragility, conflict, and violence. By definition, such settings are plagued with high levels of institutional and social fragility, often with deteriorating governance capacity. In many cases, these economies are experiencing prolonged political crises or are undergoing a gradual but still fragile reform and recovery process. These circumstances complicate the process of consensus building and resource mobilization across political cycles and therefore pose a unique set of challenges in improving human capital. The importance of investing in human capital extends beyond the gains it promises in labor productivity and in ensuring that growth is inclusive and sustainable. It is also a cornerstone of social cohesion, equity, and trust in institutions. The seven countries scoring lowest on the Human Capital Index (HCI) in 2020 are all on the World Bank’s current annual list of fragile and conflict-affected situations (FCS). On average, countries affected by conflict and violence, compared with the rest of the world, are significantly further away from reaching the productivity frontier. Shocks, such as armed conflict or natural disasters, have a lasting impact on human capital. Some pathways for this impact are obvious, including the destruction of human potential through combat deaths and casualties of natural calamities; damage to critical infrastructure and institutions, such as hospitals and schools; and the loss of skills resulting from mass displacement. But the impact of these shocks on human capital reach farther. For instance, emerging evidence shows that the destructive impacts of armed conflict on health and educational outcomes persist long after the fighting stops—extending to future generations not yet born when the conflict occurred.

Classic studies of conflict and human capital have given central attention to health impacts

33 World Bank (2020e).
34 Kim (2018).
35 These countries are the Central African Republic, Chad, Liberia, Mali, Niger, Nigeria and South Sudan.
36 Corral et al. (2020).
The link between violent conflict and a range of negative health outcomes among children has been established causally. For example, the physical development of children who were exposed to the 2002–07 civil conflict in Côte d’Ivoire was stunted, and this negative impact increased with the length of exposure to the conflict. The impact on human capital increases with increasing conflict severity. Children living in areas of Nigeria that were heavily affected by the Boko Haram insurgency had lower weight-for-age and weight-for-height z-scores and higher probability of wasting than children living in less-affected areas.

The intensity of conflict also determines the extent of human capital depletion. For instance, at aggregate level, the distance from the HCI frontier (an HCI score of 1) increases with the intensity of conflict, even among FCS countries. Countries with high-intensity conflict, defined as having at least 10 conflict deaths per 100,000 people, with

---

37 Minoiu and Shemyakina (2014).
38 A z-score is a measure of how many standard deviations below or above the population mean a raw score is. See Ekhator-Mohayode and Abebe Asfaw (2019).

---

**Figure 1.10: Human capital and severity of conflict**

Source: Corral et al. (2020) with updated HCI data for 2020.

Notes: FCS = fragile and conflict-affected situations. Economies in high-intensity conflict are defined as having at least 10 conflict deaths per 100,000 population according to the Armed Conflict and Event Data Project (ACLED) and the Uppsala Conflict Data Program (UCDP), while also experiencing a total of more than 250 conflict deaths according to ACLED, or more than 150 conflict deaths according to UCDP.
a minimum of 150 casualties, have consistently scored lower on all components of the index, compared with other FCS and non-FCS economies (Figure 1.10).

Conflict can have adverse effects on human capital across generations. Well-being and health outcomes among women in Nepal exposed as children to the country’s post-1996 civil war were significantly worse than for those women and children who were not exposed to conflict. Not only did the first-generation victims show significant reductions in final adult height, but when those conflict-exposed victims had children of their own, they provided the opportunity cost of education, since many children start working early to support their families.

Box 1.5: Schooling for Syrian refugee children in Jordan

The government of Jordan has adopted a policy of offering refugee children tuition-free access to the public education system, while also providing accredited schools in refugee camps. As a result, overcrowding has occurred in schools in some locations. Despite these measures, access to school for refugee children is still limited. Only about 152,000 of the estimated 236,000 Syrian refugee children present in the country are enrolled (64 percent). Figure 1 paints a stark picture of the enrollment decline by age among refugees. It shows that enrollment significantly tails off after age 11, more so for boys than for girls. This is driven by several factors, including poverty (since most families can’t cover the auxiliary costs of education, such as transportation and school materials); early marriage (which is also evident in recent household surveys); and increased opportunity cost of education, since many children start working early to support their families.

Reports suggest that bullying at schools and the absence of a safe learning space impedes learning for Jordanian boys as well as Syrian refugees, and the Jordanian government is taking measures to address this issue. In addition, important reforms such as ensuring universal enrolment for 5-year-olds in pre-primary education apply to all inhabitants of Jordan, including Syrian refugee children.

Figure 1: Net enrollment rate of Syrian refugees in formal education in Jordan

![Figure 1: Net enrollment rate of Syrian refugees in formal education in Jordan](image)

Source: Krafft et al. (2018).
Notes: Data only include refugees registered with the UN High Commissioner for Refugees (UNHCR).
their children also suffered reduced weight-for-height and body mass index z-scores, on average. Women exposed to the conflict during childhood had more children and lived in poorer households as adults. The combination of these two factors may decrease parents’ ability to invest in their children’s human capital during critical phases of physical and cognitive development and therefore propagate these impacts intergenerationally.39

Human capital depletion in FCS countries also happens through reduced and unequal access to education and poor learning outcomes among those who do have access. Refugee and internally displaced children embody the losses of educational human capital associated with armed conflict. Conflict in Syria, for example, has led to disruptions in education for millions of children, including over a million who have been forced to flee to neighboring countries.40 Jordan hosts one of the largest populations of Syrian refugees and has made concerted effort to provide access to education for refugee children. Yet, Syrian refugee children in Jordan experience delayed entry into school and early exit, with enrollment rates dropping sharply from around age 12, as refugee children come under pressure to work and help support their families (Box 1.5).41

Globally, refugees access education at much lower rates than other children. In 2016, only 61 percent of refugee children attended primary school, compared to 91 percent of all children. At the secondary level, 23 percent of refugee children are enrolled, versus 84 percent of eligible young people worldwide.42 These shortfalls are especially concerning, because the number of refugees and displaced people worldwide has risen steadily through the past decade and now stands at its highest level since World War II.

The intergenerational impact of conflict and violence extends to losses in educational attainment for children not even born when fighting took place. For example, exposure to the Rwandan genocide in utero decreased educational attainment by 0.3 years and the likelihood of completing primary school by 8 percent.32 The impact on years of schooling was stronger for females and for individuals exposed to the genocide in the first trimester of gestation. Each additional month of exposure in utero decreased educational attainment by 0.21 years of schooling. Through in utero exposure, conflict-related disruptions of fetal cognitive development may affect children’s subsequent cognitive capacities, educational outcomes, and earning power as adults.

How can fragile countries and development partners confront the losses of human capital driven by conflict? The best solution is to prevent fragility, conflict, and violence from engulfing countries in the first place. But when conflict does erupt, effective delivery of health and education services tailored to FCS conditions is vital. Only the preservation and rebuilding of human capital can enable countries to durably escape cycles of fragility and violence.

Yet, the delivery of health and education services in FCS poses daunting challenges, not least because of the extreme diversity of FCS contexts. However, much has recently been learned from the experiences of various countries.

In Afghanistan, for example, following the withdrawal of the Taliban in 2001, the Ministry of Public Health (MOPH) had to provide emergency relief services to address the grave health situation throughout the country. Yet the health system was in ruins after decades of warfare and neglect. As

---

40 Sieverding et al. (2018).
41 Tiltnes, Zhang, and Pedersen (2019).
42 UN High Commissioner for Refugees (UNHCR 2017).
43 Bundervoet and Fransen (2018).
they rolled out emergency health services, including in many areas still subject to conflict, health officials had to plan for the future, which included rebuilding and sustaining a functional national health system. Acknowledging its capacity limitations and with technical assistance from the international community, the MOPH led the creation of an innovative public-private partnership framework for health service delivery in Afghanistan.44 This delivery model has improved key health indicators under highly challenging conditions and has been recognized as an example for other post-conflict countries.45

Without adequate health financing, health service delivery simply will not happen. The ongoing Syrian crisis has underscored that country authorities, donors, and international partners must coordinate their efforts to ensure that health and other essential services for refugees can be sustainably paid for. An important resource to facilitate such durable support came with the 2016 launch of the Global Concessional Financing Facility (GCFF). Led jointly by the World Bank, the United Nations, and the Islamic Development Bank, the GCFF is a global platform designed to deliver concessional funding to middle-income countries that provide a global public good by hosting large numbers of refugees. GCFF resources enable governments in host countries to offer expanded services to refugees, while continuing to meet the needs of their own citizens. Early GCFF concessional loans reduced the acute financial burden on Lebanon and Jordan, two countries on the front lines of the Syrian refugee response. Subsequently, the GCFF has worked to smooth the transition from humanitarian assistance to development by providing medium- and long-term concessional finance.

Even more than other countries, economies in FCS need education systems that can promote learning, life skills, and social cohesion. Only by securing broad dissemination of these capacities in the population through quality education can countries build lasting foundations for peace and economic recovery. But the challenges in delivering equitable, quality education is not straightforward.

Some of the greatest service delivery challenges in conflict-affected countries involve education for displaced populations and host communities. Over the years, various flexible learning strategies have been fielded across different settings. Learning from these global experiences, there is a consistent move away from providing refugee education in parallel systems that may lack qualified teachers, consistent funding, ability to provide diplomas, and quality control. Ethiopia’s Refugee Proclamation, for example, gives refugees access to national schools and gives host children access to refugee schools. Iran decreed in 2015 that schools accept all Afghan children regardless of documentation. Turkey has committed to include all Syrian refugee children in its national education system by 2020.46 The inclusion of refugees in national education systems dramatically expands educational opportunities for refugees. But the process remains fraught with challenges related to system capacities, persistent access barriers, quality, and resources. Furthermore, the

The lack of timely, reliable, and actionable data and a robust measurement agenda are also factors hindering progress in human capital accumulation in FCS economies. Although high-quality data are critical for diagnosing deficiencies and formulating targeted policies and programs to enhance human capital, such data are not readily available across many countries that are in the midst of, or recovering from, fragility and conflict. For instance, for some of the countries that

---

45 World Bank (2018b).
46 UNESCO (2019).
are classified as FCS as per the World Bank 2020 classification, the HCI score cannot be calculated. This may be because data informing various HCI components either do not exist or are outdated. Even when the index can be calculated compatibly with the HCI data inclusion rules (see appendix A), it might still not fully capture the deterioration of human capital that can follow the rapidly changing reality of countries in conflict. In the case of Yemen, available data for index components mostly predate the conflict and might not fully represent the effect of the conflict on schooling or child health. Worse still, comparable data for refugees and hosts is almost non-existent in countries afflicted by fragility and conflict.

Collecting high-quality data requires sustained and deliberate efforts. In light of other pressures in situations of violence and conflict, measurement is rarely a priority. However, collecting high-quality data that address stakeholders’ data needs is feasible in these settings. For instance, mobile phone interviews have been used for data collection during the Ebola crisis in Sierra Leone and to inform a response to drought in Nigeria, Somalia, South Sudan, and Yemen. Likewise, satellite images and machine learning algorithms were employed to address the lack of a sampling frame in Democratic Republic of Congo and Somalia. When data collection is hampered by security concerns for enumerators, locally recruited, resident enumerators can make it possible to collect relevant, reliable, and timely evidence that can shed light on the plight of the most vulnerable populations. These efforts can move the needle on addressing persistent data deprivation in FCS economies.

Protecting and rebuilding human capital in settings of fragility and conflict are crucial to restore hope in these countries. They are also critical for reaching global poverty goals. Over recent decades, poverty has become steadily more concentrated in economies in FCS. Fragility and conflict deplete human capital. Yet societies must rely heavily on human capital to recover from fragility and conflict. This paradox underscores the importance of health and education services in FCS settings. Delivering these services lays the foundations that will enable countries to emerge from cycles of violence and return to peace, stability, and development. Overcoming systemic barriers will simultaneously require careful coordination between humanitarian and development partners and a whole-of-society approach.

Notes: The Human Capital Index ranges between 0 and 1. The index is measured in terms of the productivity of the next generation of workers relative to the benchmark of complete education and full health. An economy in which a child born today can expect to achieve complete education and full health will score a value of 1 on the index. Lower and upper bounds indicate the range of uncertainty around the value of the HCI for each economy.
**Box 1.6: Where did the HCI rankings go?**

The 2020 update does not report rankings for the 174 countries with an HCI score. There are four reasons for this.

First, coverage of the index has increased by 17 countries, from 157 countries in the inaugural 2018 HCI to 174 countries in 2020. So, for instance, a rank of 37 out of 157 cannot be compared with a rank of 37 out of 174. Given the change in HCI coverage between 2018 and 2020, simple comparisons of rankings as an indication of a country’s progress over time are meaningless.

Second, even if comparisons were restricted to the set of countries that are part of both the 2018 and 2020 versions of the index, rankings artificially inflate small differences in HCI scores. For example, there are eight countries clustered between HCI scores of 0.60 and 0.61, so if one of those countries at 0.60 improves by just 0.01, it would move up eight places in the ranking. By contrast, there are just two countries between 0.70 and 0.71, and so if one of those two countries were to improve its score by 0.01, it would only move up one rank.\(^{a}\)

Third, rankings suppress information on the absolute gains and losses countries have made on the HCI. Consider for example the comparison of HCI 2020 and HCI 2010, which is graphed in the left panel of Figure 1.12.\(^{b}\) Most countries have improved their human capital outcomes, reflected by the fact that they are above the 45-degree line in the figure. Rankings cannot convey these gains (or losses), because they only present the positions of countries relative to each other. This is illustrated in the right panel of Figure 1, which plots the same information for 2020 versus 2010 but in rank terms. Even countries that have made gains in human capital accumulation may fall below the 45-degree line simply because of their position relative to other countries. In addition, points in the right panel are more spread out compared with those on the left, illustrating how ranks artificially magnify small changes, as stated above.

**Figure 1: Changes in HCI scores and ranks, 2010-2020**
Fourth, and most important, there is no need to focus on country ranks because the index itself is expressed in units that are meaningful. Because the HCI is measured in terms of the productivity of the next generation of workers relative to the benchmark of complete education and full health, the units of the index have a natural interpretation: a value of 0.50 for a country means that the productivity as a future worker of a child born in a given year in that country is only half of what it could be under the benchmark. Rankings place an inordinately large focus on the fact that a country with an HCI of 0.51 is ahead of a country with an HCI of 0.50. But this interpretation misses the more critical issue, which is that in both countries, children born today will grow up with half their human capital potential unfulfilled. This is vastly more important than whether one country is “ahead of” another.

This problem is amplified by the fact that the components of the HCI are measured with some error, and this uncertainty naturally has implications for the precision of the overall HCI. To capture this imprecision, the HCI estimates for each country are accompanied by upper and lower bounds that reflect the uncertainty in the measurement of HCI components. In cases where these intervals overlap for two countries, this indicates that the differences in the HCI estimates for these two countries should not be overinterpreted, because they are small relative to the uncertainty around the value of the index itself. Rankings further amplify these minor differences.

The construction of an HCI for 2010 is described in the following chapter.
2 Human Capital Accumulation OVER TIME
As the first update of the HCI, the 2020 release is an opportunity to look at the evolution of human capital outcomes, as measured by the HCI, across countries over time.

Unlike indices that aggregate laws or regulation, which can be modified by swift government legislative or regulatory action, the HCI is based on outcomes that typically change slowly from year to year. Some of them—such as stunting and educational test scores—are measured infrequently, every three to five years. As a result, changes in the HCI over a short period are small and might simply reflect updates to components that are measured sporadically. In contrast, the analysis of longer-term trends has a more solid basis, given the scope for smoothing out short-run idiosyncrasies.

This chapter examines trends in human capital over time. Section 1 discusses the construction of an HCI for 2010 and the evolution of the HCI between 2010 and 2020. Section 2 unpacks these dynamics by looking at changes in the components of the HCI. Section 3 further sharpens the country and policy focus. Drawing lessons from case studies, it shows that a longer-run perspective on country trajectories can highlight promising policies, including the role that a whole-of-society approach, steady political commitment, domestic resource mobilization, and evidence-based policies can play in human capital progress.

### 2.1 Human Capital Accumulation Over the Past Decade

To track progress over the past decade, a version of the HCI has been calculated for 103 economies using component data in or near 2010.

Data used to populate the 2010 HCI have been carefully selected to maximize comparability with the 2020 HCI. In particular, only those countries where learning scores were measured by the same international assessment in 2010 and 2020 enter the comparison (see Box 2.1). This requirement for test scores from the same testing program proved the main constraint to building large and representative coverage, and the resulting 2010 sample is, unsurprisingly, skewed toward richer countries that tend to have more complete and better quality data. For example, the sample does not cover South Asia, since none of the seven countries in the region with an HCI in 2020 have learning data in 2010 from the same representative international test assessment as in 2020. The average HCI in 2020 for those economies that also have an HCI in 2010 is 0.62, while it is 0.48 for economies not included in the sample (Table 2.1). The potential bias is largest in the East Asia and Pacific region, where the HCI is 40 percent higher in countries with a 2010 HCI than in those without (gross domestic product [GDP] per capita is 88 percent higher).

As measured by the HCI, human capital improved in most countries in the last decade. Figure 2.1 plots HCI 2020 scores against HCI 2010 scores, likely reflecting underlying secular trends in various dimensions of human capital. On average, the HCI increased by 2.6 points between 2010 and 2020.
For countries in which the HCI scores improved—about 80 percent of the sample, depicted above the 45-degree line in Figure 2.1—scores increased by an average of 3.5 points. One economy in four that experienced a rise in the index had increases above 5 points. This means that, in those countries, the productivity of future workers approached the frontier by 5 percentage points—a substantial...
Box 2.1: Ensuring comparability across time in the HCI

The 2020 update of the HCI also reports a version of the HCI calculated for 2010, offering an opportunity to track progress on human capital outcomes. The outcome measures that are used to calculate the HCI typically register only small changes from one year to the next. A time frame of 10 years allows the index to track real underlying change in human capital outcomes over a longer period, smoothing out short-run idiosyncrasies. The HCI for 2010 is calculated for 103 countries where comparable data are available, and it provides a benchmark year for countries to measure changes over time as well as the pace of their progress.

The data used to populate the 2010 HCI are selected to be “near” 2010 and to maximize comparability with 2020. This is straightforward in the case of child survival rates that are updated annually and adult survival rates that are updated every two years. While enrollment rates used to calculate the EYS are reported annually for some countries, others may have significant gaps in their time series. In the case of gaps in enrollment for 2010, data are imputed using an annualized growth rate derived from available enrollment data for the country.

In the case of more sporadically reported stunting and test scores data, the surveys and tests used to populate the two time periods are selected to typically be at least five years apart and as close as possible to 2010 and 2020. In the case of test scores, an additional requirement that both data points come from the same or a highly comparable testing assessment program ensures comparability over time. The five exceptions are Algeria, where harmonized test scores from the Progress in International Reading Literacy Study (PIRLS) or the Trends in International Mathematics and Science Study (TIMSS) in 2007 are used to populate the 2010 HCI, while harmonized test scores based on the Program for International Student Assessment (PISA) in 2015 are used to populate the 2020 HCI; and Morocco, North Macedonia, Saudi Arabia, and Ukraine, where data from PIRLS or TIMSS in 2011 are used for the 2010 HCI, while data from PISA 2018 are used for the 2020 HCI. To maximize comparability with PISA, only secondary-level scores from TIMSS and PIRLS are used to calculate the 2010 HTS for these five countries.

Finally, while child survival, EYS, and harmonized test scores are essential to calculating an HCI, the fraction of children not stunted and adult survival rate both act as proxies for latent health. Consequently, the HCI can be calculated using either one of these proxies if both are not available. To ensure comparability in HCI scores over time, the same health proxies are used to calculate both the 2010 and 2020 scores. This means that if data for stunting are unavailable in 2010, they are not used to calculate the HCI for 2020, and vice versa.

---

*a* Adult survival rates are the complement of mortality rates for 15–through 60-year-olds, reported for five-year periods by the United Nations Population Division. These data are linearly interpolated to produce the annual estimates for countries used to calculate the HCI. See the section on Adult Mortality Rates in Appendix B for more details.

*b* The methodology to fill in gaps in enrollment data is described in detail in the Expected Years of School section of Appendix B.

*c* See Appendix A for a detailed description of how HCI components are aggregated to calculate the final index.
Over time, there is convergence in the Human Capital Index. That is, in economies starting at lower values of the HCI in 2010, human capital improved more rapidly than in economies where the HCI was higher to being with, even after accounting for initial GDP per-capita.¹

The economies with the largest gains include the Macao Special Administrative Region of the People’s Republic of China, Albania, the Russian Federation, Côte d’Ivoire, and Azerbaijan. A variety of factors account for these improvements: improved learning as measured by higher test scores (Macao SAR, China, Albania), better health (in the case of Russia, specifically improvements in adult survival, marking a rebound from the drop in life expectancies in the post-Soviet era)², and school enrollment (at the pre-primary level in Azerbaijan, at the primary level in Macao SAR, China, and Côte d’Ivoire, at the secondary level in the Russian Federation).

Some countries experienced modest declines in the index. These include the Republic of Korea, Greece, Bulgaria, and Italy, where the index fell by about 2 HCI or more points. Among the 10 countries with the largest drops, eight are European countries, and only one of the 10 is not a high-income economy. These decreases in the HCI can be mainly traced back to drops in test scores.

As incomes increase, on average, human capital improves. Panels a and b of Figure 2.2 indicate the direction of change of the HCI from 2010 to 2020, denoted by the dots and the arrow points respectively. The slopes of the arrows signal the rate at which rising per capita income is associated with more human capital. The pace is quite uniform across country income groups. However, in low-income countries, human capital improved slightly more quickly relative to GDP per capita. With health accounting for an important share of improvement in the index, especially in low-income countries (see section 2.2), a steeper slope in the HCI-GDP relationship likely reflects global gains in health, such as better and less expensive treatments and improved technology, which benefited all countries but brought about larger advances in poorer countries.

Regional and income group averages mask significant differences in individual country trajectories, which are depicted in Figure 2.2, panel c. For example, in Azerbaijan, human capital outcomes increased by 0.08 (from 0.50 to 0.58), while there was almost no change in the country’s GDP per capita. By contrast, Lithuania experienced only a small increase in the HCI despite a significant increase in per capita income.

Looking back over the last decade shows that both girls and boys have made strides in improving human capital. Sex-disaggregated data are available for 90 countries in the comparison sample over time (Figure 2.3). The average gender ratio is similar in circa 2010 and circa 2020, at about 1.06 in favor of girls. However, this stable average masks considerable differences at the country level. Around 2010, in all but seven economies, the HCI was higher among girls than among boys. Among the seven economies where girls were at a disadvantage, the girl-boy ratio improved in Cameroon, Chad, and Côte d’Ivoire but did not reach full gender parity in the last decade. These are the countries in the lower left quadrant of Figure 2.3, above the 45-degree line and below the horizontal red line. Meanwhile, in Benin, Burkina Faso, and Morocco, girls fully caught up with boys,

¹ All the components of the HCI, and the HCI itself, are bounded above. For example, adult and child survival rates cannot be larger than 100 percent, and the maximum number of learning-adjusted years of school between ages 4 and 17 is fixed at 14. This means that the absolute size of improvements become smaller as countries get closer to the upper bound.

² Smith and Nguyen (2013).
In Togo, the gender gap in HCI slightly widened in favor of boys. Both boys and girls’ outcomes were improved during this time period. The widening gender gap is driven by different rates of improvement among boys and girls. In expected years of school, girls’ outcomes improved but by a slightly lesser amount compared with boys. Meanwhile, in infant survival and stunting, boys are catching up to girls, closing the gender gaps towards parity.

Even surpassing them in the latter two countries. Among the 83 countries in which the HCI was higher for girls in 2010, the ratio in favor of girls had widened in 34 countries. However, a favorable female-male ratio in the HCI does not capture gaps in other areas of human capital development, such as labor force participation. In many countries, women participate in the labor force at far

---

**Figure 2.2: Human capital and GDP per capita: Changes over time**

- **a. Changes by income group**
- **b. Changes by regional group**
- **c. Changes at the country level**

*Notes: Panel A (panel B) plots the average HCI for income groups (regional groups) using the World Bank Group classification (on the vertical axis) against log real GDP per capita (on the horizontal axis) for 103 countries where data are available for both 2010 and 2020. The 2010 HCI is denoted by dots and the HCI 2020 is denoted by an arrow. Panel C plots country-level data for HCI 2010 and HCI 2020 (on the vertical axis), represented by dots and arrows respectively, against log real GDP per capita (on the horizontal axis) for the 103 countries where data are available for both 2010 and 2020. LIC = low-income countries; LMIC = lower-middle-income countries; UMIC = upper-middle-income countries; HIC = high-income countries.*
lower rates than men. This point is taken up further in chapter 4, which discusses an extension of the HCI capturing labor market utilization.

2.2 Changes in Key Human Capital Dimensions in the Past Decade

2.2.1 Component contributions to changes in the HCI

The evolution of the HCI reflects changes in the components of the index. There are considerable differences in the pace of change across components and in the extent to which they contribute to changes in the overall HCI. Similar to the analysis for the HCI 2020 cross-section, a decomposition suggests that almost one-third of changes in the HCI over the past decade are due to gains in health, as proxied by reductions in stunting and improvements in adult survival. Considered together, progress in child survival, stunting, and adult survival accounts for close to half the increase in the HCI; the remainder is explained by changes in enrollment and, to a limited extent, learning (Figure 2.4).

While countries in every income group experienced an increase in their HCI, the factors that contributed to these improvements differ across income groups, reflecting both countries’ initial conditions and their development trajectories.

---

4 This decomposition is implemented as a Shapley decomposition. For a description of the method see Azevedo, Sanfelice, and Nguyen (2012).
Low-income countries, in the sample, experienced considerable gains in child survival rates (which, on average, rose from 90.6 percent in 2010 to 93.4 percent in 2020). Low-income countries also registered growth in enrollment rates in pre-primary education (from 26.6 to 42.5 percent) and at the primary level (from 82.3 to 89.6 percent). These gains were offset in some countries by declines in measured learning. In high-income countries, which were already closer to the frontier for most components, increases in the HCI are mostly explained by gains in upper-secondary enrollment and improvements in health, as proxied by adult survival (Figure 2.5).

### 2.2.2 Changes in index components over time

The analysis in this subsection considers the evolution of components of the HCI over the last decade. On average, there has been progress on most components of the HCI, as illustrated in Table 2.2, which looks at the sample of countries with an index in 2020 and 2010.

While the HCI comparison between 2010 and 2020 is only possible for 103 countries, comparisons between these two points in time for each of the HCI components are possible for a larger (and variable) number of countries. The analysis that follows includes all countries for which data are available, in order to provide a comprehensive picture of changes in the different dimensions of human capital. The specific trajectories of individual components are discussed below.

#### Child survival

Progress in child survival over the past decade has been substantial in many countries, improving in 136 of the 173 countries for which data are available, as depicted in Figure 2.6.\(^5\) On average, the child survival rate rose from 0.96 to 0.97, which translates to 10 fewer deaths per 1,000 live births.\(^6\) At an average of 3.6 percentage points, improvements have been most significant among low-income countries, which started out with lower rates. In countries such as Angola, Malawi, Niger, Sierra

---

\(^5\) The child (under-5) mortality rate rose in Grenada, Mauritius, Fiji, Brunei, and Dominica, reported here in ascending order of the increase.

Leone, and Zimbabwe, improvements in child survival meant between 39 and 58 fewer deaths per 1,000 live births. These improvements are the result of global improvements in health but also of a combination of extension of health coverage, better maternal and childcare, and better sanitation. For example, …

7 A unique case is Haiti, where the child survival rate dropped massively and abruptly to 79 percent (79 of 100 children survive) in 2010 from 92 percent in 2009, following a major earthquake. Survival rates have since rebounded to 94 per 100 children.
Malawi, where child survival rates increased from 91 to 95 percent in the last decade, adopted several evidence-based policies financed by the government and development partners to improve child health, including the Accelerated Child Survival and Development Strategy (ACSD), Child Health Strategy, Integrated Management of Childhood Illness (IMCI), and the Roadmap to accelerate maternal and newborn survival. These policies and interventions have led to improved coverage of essential child health services and practices across the country, including immunizations (at 93 percent in 2014), exclusive breastfeeding (from 44 percent in 2000 to 70 percent in 2014), prevention of mother-to-child HIV transmission, and oral rehydration for diarrhea (up from 48 percent in 2000 to 64 percent in 2014), that have in turn contributed to improve child survival rates.8

Fraction of children under 5 not stunted
Advances in health over time are also reflected in decreases in stunting rates for children under 5, though declines have been modest, on average. The fraction of children under 5 not stunted

---

is available for comparison between 2010 and 2020 for 91 countries, out of which 42 are in the 2010–20 HCI comparison sample. Across these countries, depicted in Figure 2.7, the fraction of children not stunted increased by about 8 percentage points, on average. The countries with the largest improvements are Côte d’Ivoire (from 61 to 78 percent, an increase of 17 percentage points), Sierra Leone (from 56 to 71 percent, a 15 percentage point increase), Eswatini (from 60 to 74 percent, 14 percentage points), and India (from 52 to 65 percent, a 13 percentage point increase). The fraction of children not stunted declined in only a small group of countries: Angola (with a decline from 71 to 62 percent), Papua New Guinea (from 56 to 51 percent), Niger (from 56 to 52 percent), Vanuatu (from 74 to 71), Malaysia (from 83 to 79 percent), and South Africa (from 75 to 73).

The overall trend in stunting observed between 2010 and 2020 is consistent with its worldwide decline over the past decades. Progress resulted from a variety of factors—not only from overall economic development but also from health and nutrition interventions, maternal education and nutrition, maternal and newborn care, and reductions in fertility or reduced interpregnancy. Given the multiple determinants of stunting,
multisectoral solutions are necessary. Some examples are described in Box 2.2.9 Out of the countries for which stunting data are available, 25 are classified as fragile and conflict affected (FCS). While stunting decreased on average in these countries too, improvements in FCS countries were in the order of 3.6 percentage points, while in non-fragile countries they were in the order of 6.1 percentage points.10

**Adult survival**

Adult survival rates have been improving steadily over the last decade. In 2010, 82 percent of 15-year-olds were expected to survive to age 60, compared with 85 percent in 2020. Figure 2.8 illustrates the improvement in adult survival rates over the last 10 years; most countries are above the (dashed) 45-degree line. Countries with the greatest improvements include Eswatini, where survival rates increased by close to 25 percentage points—although from an extremely low base—from 35 to 60 percent, and Zimbabwe, where rates increased from 47 percent to 65 percent. While most of the countries with large improvements in adult survival are in Sub-Saharan Africa, survival also improved substantially in three countries in Eastern Europe and Central Asia: Kazakhstan (from 76 to 84 percent), Belarus (from 79 to 84 percent), and Russia (from 75 to 80 percent).

Many factors are behind these trends. In Zimbabwe, improvements were fueled by a combination of increased resources allocated to the health sector along with a progressive focus on results. This included the implementation of results-based financing (RBF) approaches in health centers and district hospitals, increasing from two rural districts in 2011 to 18 rural districts in 2013, eventually reaching 60 districts. The RBF in Zimbabwe initially focused on reproductive, maternal, newborn, and child health indicators and later expanded to include HIV/AIDS, tuberculosis, malaria and noncommunicable diseases. The early indications of positive performance under RBF, marked by increased coverage and quality of key maternal and child health services (a 13 percentage point increase in institutional deliveries in RBF-implementation districts, for instance) led to the scale up of RBF implementation across the country.11 Maternal mortality also saw declines through the improved coverage of maternal health services facilitated by urban and rural voucher schemes providing care to pregnant women.12 Another potential contributing factor is the decrease in HIV/AIDS prevalence and reduction in HIV/AIDS-related mortality due to the improved coverage of antiretroviral treatment. Of all adults aged 15 years and over living with HIV, 89 percent were on treatment, while 76 percent of children aged 0–14 years living with HIV were on treatment.13

Eswatini also witnessed some of the largest improvements in adult survival rates during the decade. However, the country has the lowest adult survival rate among non-fragile and conflict-affected economies in the sample. This reflects the high prevalence of HIV/AIDS, the leading cause of deaths in the country.14 Eswatini continues to experience the highest rate of HIV/AIDS prevalence globally, affecting 27 percent of 15-to-49-year-olds.15 The rate of new infections is also the highest in the world, with young women 15-24 years five times more likely to be infected with

9 Bhutta et al. (2020).
10 This differential persists even when the initial level of stunting and GDP per capita are factored in.
11 World Bank (2016).
12 World Bank (2019).
Box 2.2: Cross-sectoral interventions to address stunting

Through its effects on health and cognitive development, undernutrition early in life stunts children’s development and prevents them from reaching their full potential, in school and during adulthood. According to Bhutta et. al. (2020), interventions that target nutrition both from within and outside the health sector, through improvements in maternal education and nutrition, maternal and newborn care, reductions in fertility or impregnancy intervals, can be effective in reducing stunting in a variety of contexts. The following examples illustrate cross-sectoral engagements to accelerate stunting reduction.

Madagascar. With rates as high as 60% in some regions, stunting is a one of the most serious impediments to Madagascar’s socio-economic development. The World Bank, with co-financing from The Power of Nutrition, is supporting the Government of Madagascar’s efforts to reduce stunting through the Multiphase Programmatic Approach (MPA) to Improve Nutrition Outcomes, which aims to reach 75% of children in Madagascar over the next ten years with a high-impact package of services delivered through a strengthened integrated nutrition and health platform. The program evolves based on lessons learned from the field and on scaling-up successful and cost-effective interventions. Madagascar’s social safety net programs are also playing an important role in addressing child malnutrition and development. The FIAVOTA safety net program in the drought affected areas of Southern Madagascar had positive impacts on acute malnutrition, while the Human Development Cash Transfer program has had positive impacts on food security as well as young children’s socio-cognitive development, including language learning and social skills.

Rwanda. Over the past two decades, Rwanda has registered strong progress on poverty reduction and human development. However, the child stunting rate remains high at 38%, particularly among poorer and larger households. The government has been taking evidence-based action to combat stunting and invest in child development across multiple sectors. Social protection has been central to this effort, striking at the nexus between poverty, vulnerability, and child malnutrition. Rwanda’s flagship social safety net, the Vision 2020 Umurenge program (VUP), has received sustained World Bank support over the years, providing over a million poor and vulnerable people with income support and accompanying measures. In recent years, child- and gender-sensitive safety net interventions were introduced in the VUP that are now being expanded. These include Nutrition-Sensitive Direct Support (NSDS) and a Co-responsibility Cash Transfer (CCT), which targets the poorest households with pregnant women and/or children under age two, incentivizing them to access essential health and nutrition services. Rwanda’s game plan also includes strengthening high-impact health and nutrition interventions on the supply side, as well as agriculture interventions that improve food security and increase dietary diversity, and pre-primary level education interventions.

Pakistan. Fill the Nutrient Gap (FNG), an innovative analysis by the World Food Programme, identifies the bottlenecks that drive malnutrition across the food system, with a special emphasis on the availability, cost, and affordability of a nutritious diet. Using the Cost of the Diet software developed by Save the Children UK, the FNG estimates the minimum cost of a nutritious diet using locally available foods. By comparing this to household food expenditure data, the proportion of households unable to afford a nutritious diet is estimated. In Punjab, Pakistan, this exercise highlighted that a nutritious diet was unaffordable for two-thirds of the population, with the largest gap for the poorest 20% who are also targeted by the Benazir Income Support Program (BISP). The Government of Pakistan and the WFP jointly evaluated options to complement a cash transfer with nutrition specific interventions, comparing the impact of market-based interventions with a free provision of Specialized Nutritious Foods (SNF), and SNF provision in combination
with a fresh food voucher. A locally-produced SNF could be an effective way to reduce the nutrient intake gap caused by non-affordability.\textsuperscript{b} For instance, research among pregnant and lactating women and children under-two by Aga Khan University had found impact on some nutritional indicators. Based on this, the Government of Pakistan, together with development partners, designed a nutrition-sensitive conditional cash transfer program targeting pregnant and lactating women (until 6 months after delivery) and children up to 24 months old. The program included a combination of ante-natal care checkups, immunization, growth monitoring and nutrition education, SNF for women and for children, a small cash transfer to encourage the uptake of the services, and a condition of one-child per household enrolled at a time to encourage birth spacing. The program will be piloted before a nation-wide roll-out. The World Bank will support an impact evaluation to determine cost-effectiveness of interventions. Other initiatives are already ongoing, including a nutrition-sensitive conditional cash transfer programs supported by the World Bank in the Federal territories, Punjab Province and the merged districts of KP province, as well as increasing multisectoral collaboration between the federal government and provincial governments to improve nutrition in Pakistan.

\textsuperscript{b} World Food Programme (2019), and World Food Programme (2017)

**Figure 2.8: Changes in adult survival rates, circa 2010–circa 2020**

Notes: The figure plots adult survival rates circa 2020 HCI (on the vertical axis) against adult survival rates circa 2010 (on the horizontal axis) for 169 countries where adult survival data are available for both 2010 and 2020. The dashed line is a 45-degree line; points above (below) represent an increase (decrease) in adult survival rates between 2010 and 2020. Blue diamonds in the panels indicate countries on which data are available for both 2010 and 2020, but that are not part of the sample used for the HCI analysis of changes over time because they are missing 2010 comparator data for one of the HCI components.
HIV than their male counterparts. While the crisis is far from resolved, the country has made enormous progress in reducing the number of AIDS-related deaths, with a 35 percent reduction between 2010 and 2018.

Adult survival rates declined in only a handful of countries, among these Jamaica experienced the largest decline (less than 1 percentage point). The United States, where adult mortality rose from 106 to 110 deaths per 1,000 15-year-olds, is the richest country among this group. In 2020, the adult survival rate for the United States was significantly below the level that would have been predicted based on income.

Unsurprisingly, child and adult survival improved together, reflecting a broad improvement in the underlying health status of populations.

**Expected years of school**

Quantity of schooling, as measured by expected years of school (EYS), increased by about a half year of schooling (0.47 years to be precise) over the past decade in the 119 countries for which schooling data are available in 2010 and 2020 (Figure 2.9). These gains materialized across all levels of income (Figure 2.10). Low-income countries had the largest improvement, 0.90 years, mostly due to higher enrollment rates in pre-primary and primary education. In lower-middle-income countries, the EYS has risen by an average of 0.81 years, and most of this increase derives from higher enrollment rates in primary and upper-secondary education. Upper-middle- and high-income countries, which had the highest EYS values at the start of the period, experienced the smallest increases since 2010. Among high-income countries, about 50 percent of the rise can be explained by an increase in upper-secondary enrollment; among upper-middle-income countries, the rise stems from pre-primary and upper-secondary enrollment.

Economies that have experienced a significant increase in the EYS over the past decade include Bangladesh; Burkina Faso; Côte d’Ivoire; Macao SAR, China; and Togo. In Bangladesh, the EYS rose from 8.2 years in 2010 to 10.2 years in 2020. While many elements are behind this success, the government’s sustained effort to reduce fertility likely provided incentives to invest more in children’s schooling. Girls’ participation in secondary school was also stimulated by the Bangladesh Female Stipend Program, which has enabled the country to achieve one of its Millennium Development Goals, gender parity in education.

Of the 103 countries with an HCI in 2010 and 2020, 21 exhibit a lower EYS in 2020 than in 2010. Among these 21 countries, the median country lost 0.09 years of school. Enrollment rates have declined in some richer countries, including Bulgaria, Luxembourg, Italy, Romania, and Ukraine. In Romania in 2010–20, the EYS fell by 0.8 years, largely driven by decreases in primary and upper-secondary enrollment (see Box 2.3).

**Learning**

Progress in learning outcomes as measured by harmonized test scores has been modest over the past decade. While there are caveats to comparing test score over time (see Box 2.4), harmonized test score data from comparable testing programs are available for 103 countries circa 2010 and circa 2020. The average test scores from this sample remained virtually unchanged, at 452 (Figure 1). However, this stable average masks substantial improvements and declines in different countries over the past decade.

---

18 Case and Deaton (2020) connect the decrease in life expectancy in the United States to the “deaths of despair” phenomenon.
19 Refer to appendix C for more details on this calculation and for details on how enrollment data are imputed when missing.
**Figure 2.9:** Changes in expected years of school, circa 2010–circa 2020

![Graph showing changes in expected years of school from circa 2010 to circa 2020 for various countries.](image)

*Notes:* The figure plots expected years of school circa 2020 HCI (on the vertical axis) against expected years of school, circa 2010 (on the horizontal axis) for 119 countries where enrollment data are available for both 2010 and 2020. The dashed line is a 45-degree line; points above (below) represent an increase (decrease) in expected years of school between 2010 and 2020. Blue diamonds in the panels indicate countries on which data are available for both 2010 and 2020, but that are not part of the sample used for the analysis of changes over time because they are missing 2010 comparator data for one of the HCI components.

![Bar chart showing contribution to change in expected years of school by income group.](image)

*Notes:* Based on 103 economies with an HCI for 2010 and 2020. Results are the outcome of a Shapley decomposition at the country level and averaged by income group.
Box 2.3: Why have expected years of school decreased in Romania?

Three main factors explain why the expected years of school (EYS) in Romania have declined in the past decade (from 12.7 to 11.8 years). First, in the wake of the financial crisis of 2008–09, a decision was made to close Arts and Crafts Schools, which offered a vocational path as part of upper-secondary education. The number of students enrolled in these schools fell by more than 50 percent between 2010 and 2018, without a corresponding rise in enrollments in other types of upper-secondary education (see Figure 1). While the resident population of school-age children fell by only 7 percent during the decade, net upper-secondary enrollment rates fell from 86 percent to 77 percent in 2010–18. In short, the young people who would have enrolled in the vocational schools never enrolled in other schools. In 2015, the three-year vocational path was reintroduced, subsequently helping the system to recover.

Second, the number of out-of-school children, including primary-school-age children, has continued to increase during the past decade. Indeed, the number of out-of-school children ages 6–10 doubled between 2009 and 2018, from 43,000 to 98,000. The underlying reasons include persistent underfunding of the sector. Government spending on pre-primary and primary education is the lowest among European Union (EU) countries (see Figure 2). Moreover, Romania still lacks an early warning system to alert authorities about children who are at risk of dropping out. With the help of the World Bank and the European Commission, work is under way to implement such a system.a

Third, in 2012, the government introduced a compulsory year of schooling starting at the age of 6 (Romanian National Education Law no 1/2011, article 29, paragraph 2). This meant that, as of 2012, all children age 6 were counted as out of school if they were not in school. In 2018, some parents were still postponing enrolling their children in school at age 6, six years after the implementation of the new law.

Figure 1: Dynamics in enrollment numbers in upper secondary (index, 2010 = 100)

Figure 2: Spending on preprimary and primary education (share of GDP)

Source: Contributed by Alina Sava and Lars Sondergaard.
Source: “General Government Expenditure by Function,” [gov_10a_exp], Eurostat, Luxembourg.

Of these 103 countries, roughly half (49) saw a drop in test scores (appearing below the dashed 45-degree line in Figure 2.11), while the other half saw small increases. Among countries with improvements in test scores, Ecuador’s harmonized test score based on the LLECE test went up by 47 points from 373 to 420, while Cyprus and Qatar recorded gains of about 40 points in harmonized test scores based on TIMSS/PIRLS and PISA tests, respectively. Meanwhile, Egypt and Lebanon saw their harmonized test scores based on TIMSS/PIRLS decline by around 40 points (from 399 to 356 and 428 to 390, respectively). In Sub-Saharan Africa, test scores in Cameroon, Chad, and Madagascar dropped significantly between the two rounds of PASEC.

 Albania witnessed one of the largest improvements in learning outcomes, with harmonized test scores increasing from 397 (based on PISA 2009) to 434 (based on PISA 2018). Albania’s PISA score improvements coincide with the launch of intensive reform efforts in its education sector. The government launched the National Education Strategy (NES) in 2004, which was the first attempt to develop a long-term roadmap for the sector. The NES served as a catalyst for a range of reforms that continued to be implemented through the Pre-University Education Strategy launched in 2014. These reforms include improved teacher recruitment, compensation, and management; a revised curriculum for basic and general upper-secondary education focused on competencies; enhanced transparency and accountability through reform of the Matura (grade 12 exam), the national student assessment; reduced price and improved textbook quality through a reformed procurement process;
provision of textbook subsidies to the poorest households; a stronger focus on inclusive education; and expansion of enrollment in pre-primary and upper-secondary education.\textsuperscript{21}

A question that is often part of policy discussions is whether improvements in school access are associated with drops in learning. In this sample, there is no clear correlation between changes in years of education and test scores. However, changes in learning and in years of education appear to be positively correlated in upper-middle- and high-income countries and (albeit very weakly) negatively correlated in lower-middle- and lower-income countries.\textsuperscript{22}

While this evidence is suggestive at best, it points to the need to understand more clearly how education systems can be strengthened in poorer countries to achieve high-quality learning at the same time that access is being expanded.

\textsuperscript{22} Test scores and years of schooling series are negatively correlated within Latin America and the Caribbean (correlation of \textasciitilde0.16), the Middle East and North Africa (\textasciitilde0.28), and Sub-Saharan Africa (\textasciitilde0.14).
Figure 2.12: Changes in HCI components and income, 2010–20

Notes: Each panel plots the component average for income groups using the World Bank Group classification (on the vertical axis) against log real GDP per capita (on the horizontal axis) for countries where data are available for both 2010 and 2020. The 2010 HCI is denoted by dots and the HCI 2020 is denoted by an arrow. Panel a calculates income-group averages for the probability of survival to age 5 for 173 countries where data were available. Panel b calculates income-group averages for expected years of school for 119 countries where data were available. Panel c calculates income-group averages for harmonized test scores for 103 countries where data were available. Panel d calculates income-group averages for the fraction of children under 5 not stunted for 91 countries where data were available. Panel e calculates income-group averages for adult survival rates for 169 countries where data were available. LIC = low-income countries; LMIC = lower-middle-income countries; UMIC = upper-middle-income countries; HIC = high-income countries.
2.2.3 Dimensions of human capital and economic development

Much like the overall HCI, changes in individual measures of human capital don’t happen in a vacuum and are correlated with changes in income. Using a similar visualization as in the previous chapter, Figure 2.12 illustrates the average improvements in the Index components as per capita income rises. For example, in panel a, child survival rates are plotted against log real GDP per capita. A line connects the solid dots indicating the group average in 2010 to the arrows indicating the average in 2020. The lines all slope upward, reflecting the pattern of improved child survival globally. The lines also become shorter as they approach the top of the panel where there is less room for improvement. The gradient of the lines is also of interest, reflecting the rate at which outcomes improved with changes in per capita GDP. The steep lines, such as those for low-income countries and Sub-Saharan Africa, showcase large increases in child survival rates despite relatively small gains in per capita GDP. This is likely a reflection of improvements in global health, such as better but less expensive technologies. Conversely, flatter slopes in high-income countries, Europe and Central Asia, and North America suggest smaller gains in the outcome relative to increases in per capita GDP. The arrows are also shorter, because these countries were already near full child survival in 2010.

The patterns are similar (upward sloping with decreasing slopes as income increases) for adult survival and the absence of stunting across these income groups, though adult survival and child survival rates share the feature of steeper improvements at low income levels. Learning in low-income countries dropped marginally with respect to relatively small increases in GDP. It stayed virtually unchanged for middle- and high-income countries.

Reconstructing this picture at the country level in Figure 2.13 reveals significant heterogeneity, including dramatic improvements in outcomes despite little improvement in income (this is the case, for example, of survival in Eswatini). No country, however, showed large GDP improvement without at least some improvement in some human capital dimension.

2.2.4 Socioeconomic differences and progress in human capital

Regional and national averages provide important insights into development trajectories over time. However, they also mask the differential trends in human capital across groups within countries, particularly between richer and poorer households. The HCI relies on component data from administrative sources that cannot readily be disaggregated by socioeconomic status. Survey data—particularly from Demographic and Health Surveys and Multiple Indicator Cluster Surveys—also measure child survival rates, enrollment rates, and stunting rates disaggregated by quintiles of socioeconomic status. While these survey estimates are not always directly comparable with administrative data, they can provide insights into the rates of change in outcomes for the richest and poorest households within countries and how these affect national averages.

This subsection discusses child survival, enrollment, and fraction of children not stunted disaggregated by socioeconomic status, based on Demographic and Health Surveys and Multiple Indicator Cluster Surveys for selected countries.

---

23 For the role of technology in the progress in child survival, see Jamison et al. (2016).
**Figure 2.13:** Changes in HCl components and income, circa 2010 and circa 2020, individual trajectories

Panel a shows the probability of survival to age 5 for 173 countries where data were available. Panel b shows expected years of school for 119 countries where data were available. Panel c shows harmonized test scores for 103 countries where data were available. Panel d shows the fraction of children under 5 not stunted for 91 countries where data were available. Panel e shows adult survival rates for 169 countries where data were available.

Notes: Each panel plots the country-level averages for each component (on the vertical axis) against log real GDP per capita (on the horizontal axis) for countries where data are available for both 2010 and 2020. The 2010 HCI is denoted by dots and the HCI 2020 is denoted by an arrow. Panel a shows the probability of survival to age 5 for 173 countries where data were available. Panel b shows expected years of school for 119 countries where data were available. Panel c shows harmonized test scores for 103 countries where data were available. Panel d shows the fraction of children under 5 not stunted for 91 countries where data were available. Panel e shows adult survival rates for 169 countries where data were available.
with large changes in outcomes in the HCI dataset.24 Because these surveys are fielded predominantly in low- and lower-middle-income countries, most of the examples come from these countries. Figure 2.14 reports human capital outcomes over time, disaggregated by socioeconomic status.

24 School enrollment data by age disaggregated by socioeconomic status come from the latest update to the household wealth and educational attainment dataset first described in Filmer and Pritchett (1998). The latest version of their dataset contains 845 Demographic and Health Surveys and Multiple Indicator Cluster Surveys (DHS/MICS), with enrollment rates for 99 countries over 1990–2017. The child (under-5) mortality rates and stunting rates disaggregated by socioeconomic status come from the latest edition of the HEFPI database described in Wagstaff et al. (2019). Both datasets calculate the socioeconomic status index in the same way, using principal component analysis to aggregate responses to questions on asset ownership and housing characteristics into a household-level socioeconomic status index.
Box 2.5: Transforming a low-performing education system into Brazil’s best school network

Ceará is a northeastern state in Brazil that improved its education outcomes much faster than the rest of Brazil, in just over a decade. Home to 9 million people (4 percent of the population of Brazil) and with the fifth-lowest GDP per capita in the country, almost all of Ceará’s 184 municipalities had low levels of quality in teaching and very limited resources, spending about one-third less in per-student education than wealthier Brazilian states such as São Paulo.

Among these municipalities is Sobral, 200,000 inhabitants, which in the late 1990s suffered from a highly fragmented school system, with many poorly maintained small schools, most of which were in rural areas and had multi-grade classes. Despite a reorganization of the school network, a 2005 diagnostic found that 40 percent of grade 3 children were not able to read, 32 and 74 percent of students in primary and lower-secondary schools, respectively, were over grade-appropriate ages, and 21 percent of lower-secondary school students dropped out. Between 2005 and 2015, Sobral managed to achieve remarkable progress in educational outcomes. In 2005, Sobral ranked 1,366th in education among Brazilian municipalities. A decade later, it ranked first among 5,570 municipalities in the country in both primary and lower-secondary education, achieving learning outcomes comparable to world-class education systems as measured by PISA. Today, although its per capita GDP amounts to little over half the national average, Ceará has the lowest rate of learning poverty in Brazil, and Sobral has some of the country’s best primary schools. Education outcomes in both the region and the municipality exceed all expectations, given the socioeconomic context in which students live and learn: Sobral’s student-to-teacher ratio is relatively high, at 28.9, compared with 21.0 in Ceará and 20.3 on average in Brazil as a whole. These points suggest a high efficiency of the education system.

Ceará’s approach was driven by a mix of the following elements, whose effectiveness is supported by international evidence: 1. The provision of fiscal and nonmonetary incentives for municipalities to achieve education outcomes; 2. Technical assistance to municipal school networks to enhance teacher effectiveness and achieve age-appropriate learning; 3. The regular use of a robust monitoring and evaluation system, followed by adequate action; and 4. Giving municipalities autonomy and accountability to achieve learning: in Ceará, unlike the rest of Brazil, municipalities are responsible for the entirety of the education provided, from pre-primary to lower-secondary school.

A key factor enabling Ceará to emerge as one of Brazil’s top performers in education has been the capacity of state political leaders to insulate education from partisan politics. This has contributed to strong, sustained political leadership committed to improving the quality of education. Sobral organized its education policy under four pillars: 1. Continuous use of student assessments; 2. A focused curriculum with a clear learning sequence and prioritization of foundational skills; 3. A pool of well-prepared and motivated teachers; 4. A system of autonomous and accountable school management with school principals appointed through a meritocratic technical selection process. The municipality’s goal was to achieve the universal completion of lower-secondary education at the right age with appropriate learning. The results obtained show the effectiveness of goal setting and the importance of political leadership for education outcomes.
The COVID-19 pandemic threatens the progress made by Ceará. A recent study shows that two to three weeks of school closures in São Paulo amid the H1N1 pandemic resulted in an estimated two months in learning loss. Using this as a proxy for the COVID-19 pandemic, the paper concludes that an estimated two to three months school closure could induce a learning loss equivalent to a half-semester of a school year in Brazil (World Bank, 2020a). However, Ceará’s progress and the pillars that led it there should help the region tackle the tough job that lies ahead once the pandemic subsides.

Source: Based on Cruz and Loureiro (2020), and World Bank (2020).

As per Brazil’s Basic Education Development Index, IDEB.

Ceará’s per capita GDP was USD PPP 8,068 in 2019, compared with USD PPP 10,666 in Sobral and USD PPP 15,662 in Brazil.

d ibid.

against log GDP per capita. Panel a shows child survival rates, panel b shows EYS, and panel c the fraction of children under 5 not stunted. Each panel shows the country averages over time as dots. The top horizontal line reports the outcome for the richest quintile, while the bottom horizontal line reflects rates in the poorest quintile.

In the case of child survival, Haiti made massive strides between 2000 and 2012, increasing survival rates from 86 to 91 percent. Between 2000 and 2015, survival rates in Malawi rose from 80 to 93 percent. In Senegal, rates increased from 87 to 94 percent between 2005 and 2015. However, while each country showed declines in child mortality, the composition of these changes was quite different. In Malawi and Senegal, the length of the bars, that is, the gap between rich and poor households, shortened over time because the increase in the average child survival rate was driven by improvements in outcomes among the poorest households. In Haiti, while average rates improved, the size of the gap between the rich and poor remained constant.

There is similar variation in trends in the EYS. Burkina Faso was able to raise the EYS by two years, but the gap between rich and poor households was maintained at six years. In contrast, Bangladesh was able to increase the average EYS and also cut the gap between the richest and poorest households in half, from four to two years, between 2004 and 2016. Azerbaijan improved the EYS by one year, but the gap between rich and poor households rose from 0.5 years to 1.0 year. Box 2.6 offers an example from Sierra Leone of how a well-designed intervention can contribute to improve education outcomes for the most disadvantaged.

The fraction of children under 5 not stunted also increased in most countries in the last decade, as in the cases of Côte d’Ivoire, the Republic of Congo, and Uganda. In Côte d’Ivoire, the average fraction of

25 However, the increase in child mortality in 2010 in the aftermath of the earthquake in Haiti was massive.

26 The EYS data used to calculate the HCI rely on administrative data on pre-primary through upper-secondary enrollment, covering the 4–17 age range for a maximum of 14 years of school. By contrast, DHS/MICS surveys collected enrollment data for children aged 6 to 17 for a maximum of 12 years of school. As a result, the EYS reported in the HCI, calculated using administrative data, cannot be compared to the EYS reported in this section, computed using survey data.
Box 2.6: The immediate effects of providing free education in Sierra Leone

Although the majority of children in Sierra Leone start school, few successfully complete their secondary school education, and learning outcomes are among the lowest in the world, contributing to a significant human capital gap. The most cited reason why children drop out of school is not poor quality, however, but cost. Although out-of-pocket expenditures on education are fairly low, both in absolute terms and as a percent of household expenditure (about 3% across income groups), they can still represent a significant barrier for poor families, especially given that school fees are due in September, at the height of the hungry season.

The flagship program of the government is the Free Quality School Education Program, which was launched in September 2018. It provides selected public schools with block grants (calculated on a per-pupil basis) and school materials, such as textbooks, while mandating that these schools not charge fees. The program seeks to reduce out-of-pocket household spending on education (the “free” component in the program’s name) by eliminating or at least reducing school fees. It also seeks to raise the quality of education (the “quality” component), through the provision of textbooks and other measures. Public messaging around the program has stressed boosting enrollment: there is now no reason for parents not to send their children to school.

Earlier studies of free education in Sub-Saharan Africa looked at cohorts and focused on the long-term impacts following several years of implementation. Data collected in February and March 2019 allows us to assess the effects of free schooling on out-of-pocket household expenditures and enrollment in the first term of the program (beginning Sept 2018), as over 4,000 households that had been interviewed for the 2018 Sierra Leone Integrated Household Survey were re-interviewed then. For each child, the specific school they attended for the 2017/2018 and 2018/19 school years was recorded and linked to the Annual School Census to determine whether the school benefited from the FQSE program in the first term of 2018/19.

The main impact of the Free Quality School Education Program in the first term appears to have been a substantial reduction in out-of-pocket education expenditures by households. Over 90 percent of students at public primary and secondary schools receiving the block grants report that they are not paying school fees, up from about a third of primary-school students and almost no secondary-school students in the school year prior. In addition, about two-thirds of students at public schools not yet supported under the program also report that they do not pay school fees. The financial benefits of the program, in terms of reduction in out-of-pocket expenditures, are shared fairly evenly across the welfare distribution, although the poorest 20 percent of households receive the largest benefit as a percentage of total consumption.

Administrative data show a large increase in the number of students, but data collected from households reveals no significant change in net or gross enrollment rates. This discrepancy is not unexpected: a young and growing population like Sierra Leone’s will naturally see an increase in the number of school age students each year, and the way the program is structured gives schools an incentive to maximize their reported enrollment. In any case, there was little room for an increase in enrollment, as these rates were already high, particularly for
primary schools. Increases in secondary school enrollment can only come over time as more students successfully reach this level. There has been a small rise in the percent of 5- to 7-year-olds who start school for the first time; this is concentrated among the poorest households.

While the FQSE project has reduced out-of-pocket expenditures, the most keenly felt barrier to education for households, it remains to be seen whether this will eventually result in higher enrollment rates at the secondary level and higher levels of secondary school completion, and whether the program will be successful in improving the quality of education these students receive.

Source: Contributed by Alejandro de la Fuente based on de la Fuente, Foster, and Jacoby (2019).

children not stunted increased from 72 percent to 80 percent between 2011 and 2016, but the 25 percentage point gap between rates in rich and poor households remained unchanged. By contrast, Uganda was able to increase the fraction of children not stunted while also modestly closing the rich-poor gap. The gap narrowed from a difference of 20 to 16 percentage points between 2000 and 2016. In the Republic of Congo, the rich-poor gap initially increased, as the fraction of children not stunted increased from 71 percent to 78 percent between 2005 and 2011. However, the country was able to maintain momentum in reducing stunting while also reducing the difference between rich and poor households from 24 to 16 percentage points between 2011 and 2014.

This analysis highlights that countries vary significantly in the extent to which gains in human capital outcomes are distributed across the population. Addressing these rich-poor gaps in human capital must remain a priority for governments because, in many cases, the returns to investment in the human capital of disadvantaged groups, especially early in life, are the highest. However, related evidence shows that, among low- and middle-income countries, government redistributive policies do, on average, as good a job of reducing human capital inequality as does increased national income.27

At the same time, the experiences of countries like Senegal, Bangladesh, and Uganda show that countries can sometimes decouple children’s human capital outcomes from the income differences among their households.

The following section takes an in-depth look at the experiences of a selected set of countries to understand how concerted government action can deliver marked improvements in national outcomes linked to human capital over time and also reduce rich-poor gaps within countries to achieve greater equity.

2.3 A LONGER-RUN VIEW OF COUNTRY PROGRESS28

Human capital is a central driver of sustainable growth and poverty reduction. However, even for governments that recognize the importance of investing in the human capital of their citizens,
the process of designing policy and building institutions that foster human capital accumulation can be complex, with the benefits taking years and even decades to materialize. This is evidenced in the earlier sections of the report that show only modest annual progress for the average country on the HCI.

A comprehensive understanding of how countries can improve their human capital outcomes requires an analysis that adopts a longer time frame and identifies the many aspects of government intervention that can lead to positive change. By allowing a richer understanding of countries’ development trajectories, identifying the policies and institutions that proved critical to improving outcomes, and documenting the challenges involved in maintaining momentum, a comparative case study approach offers this depth of information.

This section presents the experiences of four countries that have made notable improvements in their key human capital indicators over roughly the last decade: Singapore, the Philippines, Morocco, and Ghana. The case studies illustrate how policies, programs, and processes that the governments of these countries adopted improved human capital outcomes, documenting three interrelated aspects of the countries’ trajectories: Continuity—sustaining effort over many political cycles; coordination—ensuring that programs and agencies work together; and evidence—building an evidence base to improve and update human capital strategies.29

The four countries featured in this section were selected because they have all prioritized investments in key human capital outcomes in recent years. However, they vary considerably in their levels of development, their choice of policies and programs to develop human capital, and the outcomes they achieved.

With a score of 0.88, the Southeast Asian island state of Singapore is one of the top performers on the HCI. It has a population of 5.7 million and a per capita GDP at 2011 PPP of US$96,477, making it the richest of the four countries studied here. Singapore has built a world-class education system with an increasing emphasis on analytical skills, teamwork, and creativity. The success of these efforts is evident in the increase of mean years of schooling from 4.7 in 1980 to over 11.2 in 2019.31 In the health sector, Singapore’s life expectancy at birth increased from 67 in 1965 to 83 in 2017, while infant mortality has been on a downward slope, from 27 in 1965 to 2 in 2017.32 Despite this enviable position, the country’s prime minister has stated that “the job is never done,”33 identifying active healthy aging and early childhood education as areas for improvement.

The Philippines, with a population of 104.9 million, is the eighth most populous country in Asia (and the most populous country included in this analysis) and has a per capita GDP at 2011 PPP of US$8,123. The country’s HCI score of 0.52 means that children born in the country today will fail to achieve almost half their potential. The importance that governments in the 1970s accorded to mass education in the country jump-started an expansion in school enrollment, with primary gross enrollment rates at about 100 percent and rates nearing 90 percent at the secondary level in

---

29 This approach is based on that used in the World Bank’s Human Capital Project (HCP), taking a whole-of-government approach.
30 World Bank national accounts data, and OECD National Accounts data files.
32 World Development Indicators.
However, while access has increased, quality remains an issue, with 15-year-old Philippine students scoring lower than students in nearly all other participating countries in the latest round of PISA in 2018.

Morocco, located in the Maghreb region of Africa, has a population of 33.7 million and a per capita GDP at 2011 PPP of US$7,641. The country’s commitment to human capital development has led to remarkable gains in the health of its citizens. The government has launched efforts to combat child and maternal mortality while controlling fertility rates through intensive, sustained family planning programs. A diligent immunization policy has meant that 91 percent of Moroccan children are now fully immunized. These efforts have improved human capital outcomes for the country, reflected in an HCI score that increased from 0.45 in 2010 to 0.50 in 2020.

Finally, Ghana in West Africa has a population of 28.8 million and a per capita GDP at 2011 PPP of US$5,194, making it the country with the lowest income in this sample. Despite limited fiscal space, Ghana’s commitment to improving human capital and innovative policies have led to marked improvements in the outcomes of its citizens. Since the government introduced education reforms after a major national economic crisis in 1983, primary enrollment rates have increased substantially, for example, from 67 percent to 95 percent between 2000 and 2017. Increasing school enrollments and increased access to education have led to an influx of students who are more likely to come from disadvantaged families. Despite this, Ghana’s harmonized test scores have not declined. Stunting in children under the age of 5 has fallen significantly, from 22.7 percent in 2011 to 17.5 percent in 2017.

The trajectories of policies in these countries indicate a strong focus on continuity of government support across political cycles, coordination between sectoral programs and among different levels and branches of government, and evidence-based policies. While all four countries did not implement all of these policy directions, the case studies point to the whole-of-government as an approach with enormous potential to build human capital in a wide variety of development contexts.

Sustaining political commitment to human capital development

Continuity of commitment and effort over successive governments is key to reaching any long-term goals, but especially in growing human capital, which can take decades and even generations. While not all politically stable countries were able to maintain a sustained focus on human capital, ensuring this continuity is easier if the country in question enjoys political stability, as in the cases of Singapore and Ghana, the latter characterized by a stable, multiparty democracy since 1992.

By contrast, a consistent approach to building human capital has been harder to achieve in Morocco, where political commitment to education across successive governments did not extend to other policies critical to improving human capital outcomes. In the Philippines, although several successive political administrations have adopted and sustained robust strategies to build the human capital of the population, they have not succeeded in growing sufficiently the capacity and good governance needed to implement these efforts on the ground.

---

36 Note however, that as indicated in appendix C, as in a handful of other countries, comparisons for learning in Morocco refer to different international testing programs.
In addition to political commitment, human capital development requires adequate and sustainable funding. In particular, domestic resources are central to achieving development objectives. Countries can enhance the quality and foster the legitimacy of tax systems by strengthening the operational capacity of tax administrations. However, doing so can be a challenge for developing countries with limited resources. Some countries have also found innovative ways to finance the necessary policies.\(^{38}\)

For example, the Singapore government has been able to mobilize domestic resources through the Central Provident Fund (CPF), which has played a critical role in financing infrastructure, housing, and other vital investments. Each individual and his or her employer make monthly contributions to the CPF that are distributed among three accounts owned by the individual: (i) an ordinary account for housing and retirement purposes; (ii) a special account that is primarily for retirement; and (iii) a Medisave account that is used to cover medical expenses. The government supplements the contributions of low-income earners through a workfare scheme and adds to Medisave savings of senior citizens. The CPF has also underpinned health care financing through Medisave and has fostered citizens’ responsibility for their own welfare. Thus, policy makers have managed to contain the cost of providing the country’s entire population with affordable, high-quality primary health care by tailoring subsidies to the patient’s age and ability to pay and charging users high copayments financed from mandatory health savings accounts. Regulation and bulk buying of drugs have also kept pharmacy costs in check.

Levels of funding are crucial, but so is using resources efficiently. The government of Singapore has set a high standard in this respect by ensuring that expenditures are tightly managed, including by imposing severe sanctions for corrupt practices.

While successive governments in the Philippines have enacted human capital development laws that reflect principles similar to those espoused by more successful countries, they have generally failed to provide adequate financing to ensure effective implementation. The country spends 4.4 percent of its GDP on its health programs and 3.5 percent on education programs, compared with an average of 6.5 percent and 4.5 percent, respectively, for an average country at the same income level. This has resulted in understaffed and overcrowded clinics and schools, underpaid providers, inadequate infrastructure, and a lack of administrative and technical capacity, especially at local schools and health facilities. The absence of adequate funding has also hampered efforts to improve governance. Widespread fraud in the distribution of textbooks, theft of funds or supplies, and ghost workers (workers who are paid but do not carry out their jobs) in municipal health facilities are all reflected in the country’s outcomes. In the PISA 2018 exam, about four-fifths of students (81 percent) achieved lower than a minimum level of proficiency in reading, while a similarly high percentage of students performed below the minimum level of proficiency in mathematics.

The lack of adequate financing—resulting in understaffed facilities, underpaid providers, and overcrowded clinics and schools—has particularly affected the country’s low-income households and more remote regions, which now lag behind the rest of the country in terms of access to services. By contrast, Ghana’s innovative funding mechanism—the National Health Insurance Scheme (NHIS)—was designed to expand primary care coverage while also reducing inequity in access to

---

\(^{38}\) Junquera-Varela et al. (2017).
health care by exempting the poor from premiums.\textsuperscript{39} The NHIS is funded mainly by a 2.5 percent VAT on selected goods and services, 2.5 percent from the Social Security and National Insurance Trust (SSNIT) (largely paid by formal sector workers), and the payment of premiums. These funds enable the NHIS to provide prenatal and postnatal care, maternal health care, vaccinations, and health and nutrition education, all of which may have helped to reduce stunting rates in Ghana. As a result of the NHIS, the government has been able to devote a high percentage of its spending to the health budget (10.6 percent as of 2013), which has helped to bring down the rate of childhood stunting in Ghana in both absolute and relative terms.

\textit{Collecting and using evidence to inform policy making}

Collecting data to inform policy implementation and design is easier in a compact city-state like Singapore than in a sprawling island nation like the Philippines, but digital technologies are making it easier for all countries to collect and analyze data and to use the resulting evidence when making policies and decisions.

Singapore’s public agencies and statutory boards, its state-of-the-art digital technology, tech-savvy administrators, and experienced teachers form a robust data-collection infrastructure that feeds critical information to policy makers in real time. Policy makers use these data to assess school and student performance, control costs, help managers and teachers to make decisions at every level, and do workforce planning. For example, the Ministry of Education has installed an information-gathering mechanism that helps school administrators to assess the strengths and weaknesses of their own institution and to track student performance (using a Pupil Data Bank). The system has enabled the ministry to keep closer tabs on how individual schools are faring.

In Ghana, the government used data to effectively retarget school feeding efforts under the Ghana School Feeding Program (GSFP) after it found that the targeted population (the poor) was not being reached. Data from national poverty statistics and a food security and vulnerability analysis were combined to refine targeting and reduce leakages.\textsuperscript{40} After the retargeting exercise was completed, as of 2013, about 70 to 80 percent of the GFSP was being received by the poorest communities.\textsuperscript{41} In Morocco, on the other hand, a paucity of data has stymied improvements to the country’s Tayssir conditional cash transfer program. The Audit Office of Morocco (as cited in Benkassmi, 2020) explicitly stated in its 2016-17 report that “no quantifiable indicators are available to monitor the different programs and prepare annual progress and financial reports that enable evaluation of the performance of these programs.”\textsuperscript{42}

\textit{“Whole of government” approaches: Adopting coordinated, multisectoral strategies}

Multisectoral strategies are most likely to effectively address the complex underlying determinants of human capital outcomes. Policies that cut across sectors and lines of authority can also be especially beneficial to countries such as the Philippines that have limited resources and technical and administrative capacity. In the last 40 years, successive governments in the Philippines have adopted policies that involved more than one sector, promoted

\textsuperscript{39} Not everybody has to pay the NHIS premium. Pregnant women are exempt, as are people under 18 years of age and people age 70 and above, and individuals who are employed in the formal sector and contribute to the SSNIT. Additionally, individuals considered too poor to pay are also exempt from paying the premium. This includes beneficiaries of the Livelihood Empowerment Against Poverty (LEAP) program.

\textsuperscript{40} WFP (2013) and Drake et al. (2016).

\textsuperscript{41} WFP (2013).

integrated approaches, and encouraged greater participation by stakeholders in service delivery. In addition, many policies reflect the fact that factors beyond the social sectors affect human capital development, such as clean air, a safe water supply, and the provision of sanitation services.

The country has several programs that are organized on multisectoral lines. An example is the Pantawid Pamilya Pilipino Program (4Ps), which provides cash to chronically poor households with children aged between 0 and 14 years old who live in poor areas.\textsuperscript{43} In return, the beneficiary households are required to undertake certain activities aimed at improving their children’s health and education, such as taking them to health centers regularly, sending them to school, and going to prenatal checkups in the case of pregnant women. Thus, 4Ps integrates human capital development with poverty reduction efforts. The Department of Social Welfare and Development (DSWD) was charged with leading the program’s implementation, and worked with the Department of Health, Department of Education, Department of the Interior and Local Government, and the government-owned Land Bank of the Philippines. The 4Ps also actively involved local service providers (such as school principals and midwives) in implementation by tasking them with verifying that households were fully complying with the prerequisite conditions for the cash transfers.\textsuperscript{44}

Impact evaluation studies show that the program is resulting in improved education and health outcomes among beneficiaries, including enhanced food security, community participation, and women’s empowerment. Specifically, it has helped reduce short-term poverty and food poverty at the national scale by up to 1.4 percentage points each—a substantial reduction, given that pre-Pantawid rates were at 26.4 percent for total poverty and 12.5 percent for food poverty.\textsuperscript{45}

Ghana’s progress in decreasing stunting rates\textsuperscript{46} has also been due in large part to the multisectoral approach taken by policy makers. For example, the Ghana School Feeding Program (GSFP) links school feeding programs with agriculture development, especially smallholder production, thus helping to create new markets for locally grown food.\textsuperscript{47} Thus, the GSFP spans three different sectors—agriculture, education, and health.\textsuperscript{48} Also, initiatives aimed at improving water sanitation and hygiene in schools have helped to increase access to water and sanitation, which is a proven factor in improving health and education indicators.

The experiences of the four countries examined here highlight the importance of sustained effort to improve human capital outcomes across political cycles, sufficient resource mobilization and effective allocation across programs, data and measurement to inform and design, and multisectoral strategies that address the complex underlying determinants of human capital outcomes. These best practices are likely to assume an even greater significance in the wake of the COVID-19 pandemic, as countries attempt to mitigate the negative effects of the pandemic on human capital outcomes.

\textsuperscript{43} Eligible households received between 500 pesos and 1,400 pesos (US$11–US$32) per month, depending on the number of eligible children in the household (King 2020).

\textsuperscript{44} In 2009, the DSWD institutionalized the system as the National Household Targeting System for Poverty Reduction (NHTS-PR), and by 2011 it had shared the database with the Philippine Health Insurance Corporation, Department of Agriculture, and Department of Health to help those agencies better target the benefits of their own programs (Fernandez and Olfindo, 2011).

\textsuperscript{45} Acosta and Velarde (2015).

\textsuperscript{46} Gelli et al. (2019).

\textsuperscript{47} World Bank (2012) and Sumberg and Sabates-Wheeler (2011).

\textsuperscript{48} The GSFP is run by the Ghana School Feeding Program Secretariat under the direct supervision of the Ministry of Local Government and Rural Development. Other public partners directly involved include the Ministry of Education, the Ministry of Food and Agriculture, the Ministry of Health, the Ministry of Women and Children’s Affairs, the Ministry of Finance and Economic Planning, and the District Assemblies.
Accumulation Interrupted?
COVID-19 and HUMAN CAPITAL
COVID-19 has exacted a heavy toll in illness and lost lives and on the economy. Lacking a vaccine or effective pharmaceutical treatment against SARS-CoV-2, the novel coronavirus responsible for COVID-19, many countries resorted to large-scale nonpharmaceutical interventions (NPI) to slow the virus’s spread. These NPI resulted in an economywide lockdown of different levels of restrictiveness. These measures further amplified the disruptions that COVID-19 brought to supply chains and global trade, adding to the already dramatic economic dimension of the health crisis. A baseline forecast for GDP in 2020 predicts a global drop of 5.2 percent, the worst recession in eight decades, which is likely to push 100 million more people into poverty.

A lesson from past pandemics and crises is that their effects not only are felt by those directly impacted, but often ripple across populations and in many cases across generations. COVID-19 is no exception. Both the health and economic effects of the disease and its control measures have significant consequences for people’s human capital. In many health systems, the fight against the pandemic has crowded out other essential health services. At the same time, people’s fear of infection has led to many choosing to not seek treatment, possibly derailing years of gains against diseases like tuberculosis, HIV, and malaria.

At the same time, lockdowns translated into school closures and the shift to remote learning in some form, which can in many cases worsen learning gaps between children with a more affluent background and those who are less well off. It can also lead to widening gaps between countries, since many may not have the infrastructure in place for such an endeavor. Adding to people’s hardships are household income losses due to unemployment and reduced remittances, with effects that might be quite different across developed and developing countries.

While there is still tremendous uncertainty on the overall impact of the pandemic on human capital, it is clear that both direct and indirect pathways will matter. Those who were most vulnerable to begin with are likely to be the worst hit, and many dimensions of inequality are likely to increase. Sections 1 and 2 of this chapter discuss channels of impact from COVID-19 to human capital and their likely effects over people’s full life cycle. Section 3 discusses how the Human Capital Index (HCI) can be used to quantify some of the likely impacts of the pandemic on children and youth.

### 3.1 Transmission of the COVID-19 Shock to Human Capital

#### 3.1.1 Health system disruptions

As governments scramble to respond to the immediate consequence of the pandemic, resources are...

---

1 World Bank (2020).
2 Mahler et al. (2020b).
3 Simulations suggest that, in Ireland, 400,000 households may see a drop in their disposable income of 20 percent or more (Beirne et al. 2020). In Italy, simulations show that disposable income losses will be considerable and more pronounced for the poorest. Italian households in the poorest quintile are projected to lose 40 percent of their income (Figari and Fiorio 2020).
likely to be diverted from other health efforts that nonetheless remain critical. In past health emergencies, substantial negative indirect effects have resulted from this crowding out of nonpandemic-related health services. For example, in the 2014–15 Ebola outbreak in West Africa, closure of health facilities, health worker deaths, and excess demand placed on the health system led to further loss of lives. In Ebola-affected areas, it was reported that maternal and delivery care dropped by more than 80 percent, malaria admissions for children under the age of 5 fell by 40 percent, and vaccination coverage was also considerably reduced.4

Some of these consequences are already apparent for COVID-19. Vaccination programs in roughly 68 economies have been interrupted due to the pandemic, and some 80 million children under the age of 1 year will go unvaccinated in low- and middle-income countries as a result.5 Supply-chain breakdowns combine with forced mobility restrictions under NPI to complicate overall access to vaccines.6

Children and pregnant mothers are not the only ones who will suffer from weakened service delivery capacities and curtailed access to services. During a pandemic, most people are more reluctant to seek medical care. During the SARS epidemic in Taiwan, China, people’s fear of infection likely led to sharp drops in demand for access to medical care across the board.7 Many patients suffering from other illnesses will be unable to go for routine checkups, due to restricted movement and to avoid COVID-19 infection. Such service interruption will also likely lead to numerous deaths, many of them avoidable. For example, in high-burden countries, it is estimated that over the coming five years deaths due to tuberculosis, HIV, and malaria will increase by 20, 10, and 36 percent, respectively.8 A lesson is that, when determining how to reallocate resources for pandemic response, special attention must be given to maintaining coverage of key non-COVID interventions.9

### 3.1.2 School closures

By the end of April 2020, schools were closed or partly closed in roughly 180 countries, although schools are now slowly reopening in many jurisdictions.10 While the impact of school closures will depend on the effectiveness of mitigation from remote instruction, closures will likely result in a slowdown and loss of learning, and an increased likelihood of school dropout, particularly for the most disadvantaged and for girls.11

These human capital losses are not necessarily uniformly distributed across the population. As children learn from home, social inequalities become more salient. The closure of schools could widen already-existing gaps in education between children from better-off homes and those who come from less well-off backgrounds, as poor households’ access to technology and infrastructure is likely to be more limited. Additionally, learning from home requires more inputs from parents, and some parents’ limited capacity to guide and

5 WHO (2020a) and Nelson (2020).
6 Ibid.
7 See Chang et al. (2004).
8 See Hogan et al. (2020). These authors find that for HIV the largest impact is from interruption of antiretroviral therapy, for TB the impact is due to reduction of timely diagnosis and treatment, and for malaria it reflects the interruption of prevention programs.
9 Roberton et al. (2020) suggest that maintaining key childbirth interventions like parenteral administration of uterotonics, antibiotics, anticonvulsants, and clean birth environments could lead to 60 percent fewer maternal deaths. Maintaining coverage of antibiotics for neonatal sepsis and pneumonia and oral rehydration solution for diarrhea would reduce child deaths by 41 percent. These results are likely contingent on modeling assumptions.
10 UNESCO (2020).
11 See Azevedo et al. (2020). Girls’ educational outcomes during a crisis tend to fall more so than those of boys. This is particularly the case if parents’ perception of returns on investments for boys are greater than for girls (Rose 2000).
support their children’s learning could exacerbate inequalities.

Along with education, many children receive other services through their schools. These include meal programs, which tend to benefit poorer children. The suspension of school feeding programs could worsen food insecurity and malnutrition. The burden of making up the nutritional shortfall now falls on parents, many of whom are struggling economically due to the pandemic.\(^\text{12}\)

### 3.1.3 Income effects, price effects, and food security

The emerging literature on containment strategies highlights the large benefits—in terms of lives saved and GDP losses averted—of testing and contact tracing.\(^\text{13}\) While countries such as South Korea and Iceland successfully implemented these strategies early on in the pandemic, most countries resorted to lockdowns and movement restrictions.\(^\text{14}\) Voluntary mobility restrictions combined with government-driven lockdowns generate a significant drop in activity and aggregate demand that is leading to a considerable reduction in incomes. Nevertheless, the largest impacts to the economy are expected to come from reduced consumption due to people’s avoidance of social interaction due to fear of infection.\(^\text{15}\)

Projections show that the resulting economic fallout will be massive and potentially worse than that of the 2008–09 financial crisis.\(^\text{16}\) Lockdowns force many nonessential businesses to close and will further disrupt supply chains. Coupled with inherent uncertainty due to the pandemic, this may prompt many people to cut back on expenses, which in turn may trigger more businesses to close and more people to lose their jobs.\(^\text{17}\) The ensuing economic decline is likely to undo years of gains in the fight to eradicate extreme poverty. Accordingly, the World Bank has projected an increase in international extreme poverty for the first time since 1998.\(^\text{18}\)

Closures and decreased economic activity result in higher unemployment and income losses for many households. Households in countries that rely on remittances or seasonal migrants for income report that contributions from these sources have fallen considerably, and many households report that they expect to lose their remittances altogether (see Box 3.1). The fall in household incomes is likely to affect the poor disproportionately, as they often experience more fragile labor arrangements and, if inadequately covered by safety nets, are likely to fall through the cracks.

The income shock will probably be exacerbated by the initial price shock already observed in many countries. The pandemic has created a short-run demand shock, where the products demanded by consumers are different. As movement restrictions dissuade people from venturing out in public, many activities that would typically happen in markets, restaurants, or other commercial settings end up taking place at home. Because manufacturing of goods for restaurants, hotels, and offices differs from manufacturing for home consumption, which has now increased, shortages can temporarily arise and prices increase as a short-run response.\(^\text{19}\)

19 Hobbs (2020).
Concerns about localized food availability may not be unfounded. Due to mobility restrictions, many farmers may experience labor shortages, which can reduce yields and further strain the supply of staple foods. Small farmers may also choose to avoid going to markets to sell their goods, due to fears of contagion. Mobility restrictions and labor shortages may also prevent farmers from transporting their goods to market. This is likely to affect the availability of more perishable crops, such as fruits and vegetables. If these products cannot reach markets in time, they may simply rot in the fields, as many farmers lack adequate storage facilities.

Given that many households will experience a fall in their incomes, many households will likely experience food insecurity. This will impact the poorest households most, since they devote a larger share of their incomes to food expenditures. Households will respond to such events by limiting their food intake and/or relying more on cheaper staple foods, reducing dietary diversity. This will further worsen the nutrition of millions of people. Evidence of such scenarios is already emerging. For example, in Senegal, 86 percent of respondents to a telephone survey reported a drop in their incomes, and more than one-third indicated that they restrict their meals four to seven days a week. In Nigeria respondents state fear for their health and financial future, with many also reporting increased prices of major food items and loss of employment. In Uganda, households on average report a reduction in total household incomes of 60 percent, and a drop in food expenditures of roughly 50 percent per adult equivalent. Evidence from Uganda also points toward temporary coping mechanisms used by households, many of which increased borrowing, dipped into their savings, or invested more of their time in household enterprises.

Despite the pandemic’s severe direct health impacts, the largest effects on human capital will probably come through indirect channels. Indirect does not mean insignificant. Emerging results for a large set of rapid phone surveys fielded by the World Bank speak to indirect consequences of the pandemic that may permanently weaken countries’ human capital for generations (see Box 3.1).

The accumulation of human capital is the result of a dynamic process whose dimensions complement each other over time. Depending on an individual’s stage in life, the impact of the pandemic on this process may come through different channels and have a differential impact. Setbacks during certain stages of the life course—chiefly early childhood—can have especially damaging and long-lasting effects. For example, economic hardship can force families to prioritize immediate consumption needs, forgoing spending on health or education. Because demand for investing in human capital rises with incomes, a fall in incomes could worsen

---

20 This was observed during the 2014–15 Ebola outbreak in West Africa. See de la Fuente, Jacoby, and Lawin (2019). A similar effect is now seen in India, where nonavailability of migrant labor has interrupted harvesting activities. See Saha and Bhattacharya (2020).
21 Tesfaye, Habte, and Minten (2020).
22 Women will often sacrifice their own consumption needs in order to ensure sufficient nutrition for other members. See Quisumbing et al. (2011).

25 Mahmud and Riley (forthcoming). When surveyed, Ugandan households had yet to resort to selling productive assets to cope with the losses in income, perhaps in the hope that the income shortfall will be short-lived.
26 Bardhan and Udry (1999).
human capital accumulation for many people, especially the most disadvantaged. Figure 3.1 depicts schematically how some of these shocks can affect the process of human capital accumulation over the life cycle. On the right-hand side of the picture are some typical age-specific markers for human capital development, some of which enter as components into the Human Capital Index.

27 In some cases, the substitution effect (the relative change in prices of activities) dominates the income effect (the drop in purchasing power). For example, Miller and Urdinola (2010) present evidence of how child health has improved among children of coffee farmers in Colombia during a decline in the price of coffee. Since time spent farming is less valuable due to the fall in coffee prices, parents devote more time to their children, which translates into better outcomes for children. Schady (2004) provides evidence that, in Peru, children exposed to a crisis in the late 1980s completed on average one additional year of schooling.
3.2.1 From conception to age 5

During childhood, the link between parental income and child health is particularly strong. For example, reduced nutrition in pregnant mothers could have a substantial impact on children in utero, including long-lasting impacts on chronic health conditions and cognitive attainment in adulthood. The evidence shows that this is the case for children born during a pandemic but also for children born during conflict and economic hardship. For example, children who were in utero during the 1918 influenza pandemic had lower educational attainment and income during adulthood. The effect was even more salient among children of infected mothers. Much about the current virus remains to be learned. At the moment, the main transmission channel affecting the fetus’s human capital is expected to be through the disruption of health care and lower household income.

Birthweight is often interpreted as a key observable component of a child’s initial endowment. Children who were in utero during the 2008

---

29 See Almond and Currie (2011).
30 For example, Bundervoet and Fransen (2018) find that children exposed to the Rwandan genocide while in utero suffered lower educational outcomes. The longer the exposure in utero, the poorer the educational outcomes.
31 Rosales-Rueda (2018).
33 Savasi et al. (2020) found that 12 percent of the 77 patients in their study (in Italy) had a preterm delivery. On the other hand, Philip et al. (2020) find a reduction in preterm births in Ireland, and a reduction in very low birth weights, falling from 3.77 cases per 1,000 births to 2.17 cases.
34 See Datar, Kilburn, and Loughran (2010).
recession were born with relatively lower birth-weight, particularly in families at the bottom of the income distribution.35 This was the case for children born in those California regions that suffered unusually elevated unemployment rates after the 2008 recession.36 Similarly, in Ecuador during the 1998 El Niño floods, children who were in utero and especially in the third gestational trimester were much more likely to be born with low birthweight, and these children showed substantially reduced stature 5 and 7 years afterward.37 These health effects were attributed to drops in household income following the devastation of El Niño. Similar outcomes can unfortunately be expected from the COVID-19 shock. As low birth-weight is associated with increased likelihood of malnutrition and developmental delay, COVID-19-induced income effects may substantially affect human capital attainment for generations to come.38

Child mortality is unfortunately also likely to increase, for two reasons. The first is the disruption in maternal and child health services due to COVID-19. Early simulated values project an increase of child mortality of up to 45 percent due to health-service shortfalls and reductions in access to food in 118 low-income and middle-income countries.39 Second, economic downturns have been associated with significant increases in child mortality, with a more marked increase in lower-income countries. A meta-analysis of studies for developing countries suggests that a 10 percent increase in GDP per capita is related to a decrease in infant mortality of 4.5 percent.40 Recent estimates also show that the relationship between income and child mortality is likely higher in low-income countries, suggesting that short-term aggregate income shocks translate into an increase in child mortality of 1.3 deaths per 1,000 children among low-income countries, given a 10 percent decrease in per capita GDP.41

Stunting rates are also likely to increase due to the COVID-19 shock. Common factors related to stunting are maternal nutrition during pregnancy and nutrition during infancy, both of which will likely worsen if families have less disposable income.42 A fall in aggregate GDP could also lead to weakened health infrastructure and less funding for nutritional interventions and services.43 Existing estimates of elasticities suggest that a 10 percent increase in GDP leads to a decrease in stunting that may range from 2.7 to 7.3 percent.44 Nevertheless, aggregate elasticities may obscure the fact that many of these shocks will affect the poor and disadvantaged disproportionately. Attention must be paid to ensure these groups have access to any available support mechanisms that may mitigate such impacts.

35 See Finch, Thomas, and Beck (2019).
36 Ibid.
38 See Black, Devereux, and Salvanes (2007) and Lahti-Pulkkinen et al. (2018).
39 Roberton et al. (2020).
40 O’Hare et al. (2013) obtain this estimate through meta-analysis from a systematic literature search of studies and find a pooled elasticity of income on infant mortality of ~0.95.
41 Ma et al. (2020) find that, in low-income countries, a lockdown will potentially lead to 1.17 children’s lives lost per COVID-19 fatality averted, due to the economic contraction, significantly higher than in lower- and upper-middle, income countries (where it would stand at 0.48 and 0.06, respectively). This is due to two factors: the younger demographic structure and the higher estimated elasticity of child mortality to GDP changes in low-income countries. The authors also assume that under-5 mortality is not affected by income shocks in high-income countries.
42 See Galasso and Wagstaff (2019).
43 See Mary (2018) for a more nuanced discussion.
44 Mary (2018) suggests that the decrease may be 2.7 percent, while Mary et al. (2019) estimate it to be 7.3 percent, and Ruel et al. (2013) suggest 6 percent. It is worth noting that these analysis concentrated mostly on low- and middle-income economies.
3.2.2 The school years

With almost all countries having imposed some type of school closure due to the pandemic, students in many settings are likely to suffer learning shocks. Evidence suggests that any interruption in children's schooling typically worsens learning outcomes. This includes disruptions caused by epidemics, conflict, natural disasters, and even scheduled school vacations. US students' achievement scores appear to decline by about a month's worth, on average, during the regular three-month summer break.45

Historical experiences illustrate the impacts of large-scale school closures during a public health emergency. Meyers and Thomasson (2017) studied the effects of the 1916 polio pandemic on educational attainment in the United States. Young people ages 14–17 during the pandemic later showed reduced overall educational attainment compared to slightly older peers.46 Even short-term school closures appeared to have lasting impacts on children's educational attainment, though the study found such effects only among children who were of legal working age during the school closures.

Increased dropout rates are one relay linking emergency school closures to future losses in lifetime educational attainment. In general, as children age, the opportunity cost of staying in school increases. This may make it harder for households to justify sending older children back to school after a forced interruption, especially if households are under financial stress. Again, such effects are not restricted to public health emergencies. In Tanzania, among agricultural households, income shocks, even transitory ones, led to increased child labor and reduced school attendance.47

Evidence from natural disasters confirms that interruptions and trauma in the neurodevelopmental process can adversely affect academic performance.48 Four years after bushfires in Australia, children from areas that were heavily impacted by the fires performed worse in reading and numeracy than peers from less-impacted schools.49 The case of the bushfires underscores the importance of continued support to affected populations, since a longer-term learning divergence was found even though students did not display any differences in learning outcomes immediately after the disaster.

Further indication of the damage caused by school interruptions can be gleaned from the outcomes after the 2005 earthquake in Pakistan. Areas near the fault line were devastated, 80 percent of homes were destroyed, and schools suffered considerable damage. Cash transfers played an important mitigating role, because four years after the earthquake, households near the fault line were indiscernible, in welfare terms, from those farther away from the fault line. Enrollment rates for children residing near the fault line were not affected. However, despite the apparent return to “normalcy,” test scores for children living 10 kilometers away from the fault line were 0.24 SD below those of children residing 40 kilometers away.50

Many countries have adopted distance learning as a means to mitigate learning losses during

---

45 Cooper et al. (1996). More recent research has called this result into question. See von Hippel and Hamrock (2019) for more nuanced discussion. However, a summer break is not the same as a break during the school year.

46 Meyers and Thomasson (2017).

48 Gibbs et al. (2019).

49 Ibid.

50 Andrabi, Daniels, and Das (2020). The authors posit that this is equivalent to 1.5 school grades. To arrive at this value, the authors note that the average 15-year-old has accumulated 5.6 grades and linearly gain 0.17 standard deviations (SD) in performance per grade level in the test the authors use. This result, in the context of harmonized test scores used in the HCI, translates to a drop of 24 points.
protracted school closures. Remote teaching strategies include not only online learning, but also radio and TV programs and text nudges in those countries where digital connectivity is limited. These strategies make it less likely that negative effects of similar magnitude to other interruptions will be replicated; however, the effectiveness of these measures has yet to be determined.

The most recent global projections on the impact of school closures linked to COVID-19 suggest that, using the HCI metric of learning-adjusted years of schooling (LAYS; see Box 1.1 from Chapter 1), almost 0.6 years will be lost due to the closures. These numbers reflect the loss of schooling that comes from potential dropouts due to the loss of income, as well as the adjustment in quality due to worsened learning because of inefficient remote teaching methods. The lost schooling in the face of a mitigation strategy that has medium efficiency translates to a yearly loss of over US$ 872 in 2011 USD PPP, reaching a loss of US$ 16,000 in lifetime earnings in present value terms at a discount rate of 3 percent and assuming a 45-year work life. As children head back to school, countries with an already overextended education system may be grappling with increased demand for public education. This has occurred due to household income losses that have prompted many parents to turn to public schools. In June 2020, registration in public schools in the coastal zone of Ecuador, for example, increased by 6.5 percent, bringing some 120,000 additional students into the public system. This occurred despite the government’s offering of a 25 percent subsidy on monthly private-school tuition for parents who had lost jobs. With limited numbers of qualified teachers available, migration of students from private to public schools could worsen learning outcomes across many countries.

Thus, the impacts of school closures extend far beyond initial enrollment drops. For girls, school closures may also lead to increased exposure to pregnancy and sexual abuse. In many countries this could be worsened by policies that prevent “visibly pregnant girls” from attending school. Both shorter- and longer-term impacts are likely to affect disadvantaged families most, further widening inequalities in learning and human capital accumulation between socioeconomic groups.

Finally, a drastic change in the day-to-day lives of children and adolescents is likely to affect their mental health. The pandemic may worsen already-existing mental health issues by provoking or exacerbating social isolation, economic uncertainty, and fear. A recent study among Ecuadorian teenagers (ages 14 to 18) found that one in six teenagers reported suffering from depression, while many cited household finances and social isolation as concerns. The use of digital technology, particularly with voice and video, can ameliorate the loneliness faced by many teens and children, but these technologies are not available to all.

---

51 The simulation by Azevedo et al. (2020) implicitly assumes that income effects outweigh substitution effects that may arise in these cases. Nonetheless substitution effects may be larger, and enrollment could increase. Shafiq (2010) presents two cases: (1) Falling wages make child labor less attractive, and (2) if parents place a higher preference on education, perhaps because less educated workers bear the brunt of the crisis, then enrollment may increase.
52 Azevedo et al. (2020).
53 Ibid. Values are obtained for 157 countries. Authors model different mitigation strategies taken during remote learning, vary the length of school closures, and assume children will drop out of school due to the income shock. The yearly losses range between US$ 127 in low-income countries to US$ 1,865 in high-income countries per year.
54 Olsen and Prado (2020).
55 Bandiera et al. (2019). The determination of correctly identifying pregnancy gave school principals discretion on how to enforce the ban.
56 Golberstein, Wen, and Miller (2020).
57 Asanov et al. (2020).
58 Galea, Merchant, and Lurie (2020).
3.2.3 School-to-work transition and tertiary education

The pandemic is also disrupting human capital accumulation for students currently in tertiary education. Almost the totality of students currently enrolled in tertiary education are experiencing a new learning modality. With students in low- and middle-income countries less likely to have internet access, between-country inequalities in learning will worsen. Within countries, those at the bottom of the income distribution will also be more affected, due to lack of access to the necessary materials for remote learning. This will again exacerbate existing inequalities in human capital accumulation.

Two opposing forces may influence tertiary enrollment rates. Pandemic-induced high unemployment rates are likely to reduce the opportunity cost of attending college. At the same time, the recession will affect many households economically, and funds for attending college may not be available. After the financial crisis, enrollment rates for tertiary education in the United States went up. However, because of a substantial decrease in family incomes, student shifted away from four-year private colleges toward two-year public institutions.

Those who graduate from college now are also likely to suffer short- to medium-term wage losses. Evidence from Canada suggests that graduating during a recession is linked to significant initial earning loss due to less desirable job placements, but that this penalty fades over some 8 to 10 years. Nevertheless, the average effect hides substantial heterogeneity. Recent graduates with the lowest predicted earnings are likely to suffer the largest losses and often do not recover the lost ground after 10 years. Starting at a lower-paying job or at a less-desirable firm that does not make full use of an individual’s existing human capital may well lead to a lag in skill accumulation and result in a persistent disadvantage.

Women who graduate from high school during the pandemic may choose to respond differently than male peers to the shock and forgo college in the short term. They are also less likely to join the workforce, due to the depressed wages. Evidence from the United States suggests that women, but not men, graduating from high school are more likely to skip college during recessions because of the lower observed returns to education and because the cost of more schooling increases. For some, the alternative of child rearing may be more attractive in the short term, as was the case during the 2008–09 global recession. For others, disruptions in the supply chain may lead to unintended pregnancies as many women will lose access to modern contraceptives.

Finally, because of the depressed wages and fewer legal employment options available during a recession, crime also becomes more attractive. The longer the recession lasts, the more likely that acquired human capital depreciates and crime becomes a worthwhile option. This effect is heightened for those who have lower human capital levels and are less attached to the labor market.

59 Bassett and Arnhold (2020).
60 Dunbar et al. (2011). A similar dynamic was observed in Peru, where the opportunity costs of going to school decreased by a considerable amount because wages dropped substantially. Thus, children exposed to the crisis completed more years of education (Schady 2004).
62 Rothstein (2020) finds evidence that those who graduated during the 2008–09 financial crisis had lower wages and employment than earlier cohorts. The author shows that market conditions at the time of labor market entry matter greatly for cohorts’ employment probabilities.
63 Hershbein (2012).
64 Roughly 47 million women in 114 low- and middle-income countries could lose access to contraceptives in the scenario of a six-month lockdown or disruptions (United Nations Population Fund [UNFPA] 2020).
65 Bell, Bindler, and Machin (2017) find that cohorts that graduate into a recession are 10.2 percent more likely to commit criminal activity than cohorts who enter the labor market in nonrecession times.
3.2.4 Working life
Together with the economy, the pandemic has affected labor markets dramatically. According to the International Labour Organization (ILO), working hours during the first quarter of 2020 declined by the equivalent of 130 million full-time jobs. The organization expects that the results will be even worse in the second quarter of 2020, with the number climbing to 305 million full-time jobs.\(^{66}\) The pandemic and lockdown measures are affecting workers worldwide but are having particularly dramatic impacts for informal workers. Informal work often happens in crowded places, so that lockdown measures—when enforced strictly—make continuing with these jobs impossible.\(^{67}\) Informal workers also often fall through the cracks of social protection systems, lacking access to unemployment and health insurance.\(^{68}\)

Unemployment stints, even short ones, tend to leave a lasting mark on individuals’ earnings. For many, this will be the second “unprecedented” economic shock of their working lifetime. Workers who have longer tenures in a company, if dismissed, are likely to face a considerable erosion of skills, as many skills they have accumulated may be particular to that employer. If these workers find employment in the future, and their new job requires different skills, they are likely to experience a considerable wage penalty.\(^{69}\) Those who lose a job during a mass layoff event are likely to experience large and persistent earning losses, roughly equivalent to 1.7 years of their earnings prior to dismissal.\(^{70}\)

There is also evidence that those who have lost jobs during the pandemic could suffer far more than lost earnings. One study finds that US workers who were employed in a firm for at least six years and were then dismissed during a recession had higher mortality rates than similar workers who had not been displaced. The estimates suggest an average decrease in life expectancy for the dismissed workers between 1 and 1.5 years, likely due to increased chronic stress. Even when economic conditions later improved, the lower earnings experienced by workers who lost jobs can lead to reduced investments in health.\(^{71}\)

The pandemic and the nonpharmaceutical interventions taken are also likely affecting women more than men. The sectors typically most affected by lockdowns have high shares of female employment.\(^{72}\) School closures will likely contribute to heavier workloads for many women, mostly because women are likely to be responsible for child care in the absence of alternatives. These pressures may limit women’s paid work.\(^{73}\) Established gender norms are also likely to prevail when a family member falls ill due to COVID-19, with women in the household expected to care for the sick. On the other hand, the current shift to flexible working arrangements could benefit some workers, including women, and could promote gender equality in the labor market in some settings.\(^{74}\)

Beyond work, interpersonal violence is also on the rise, leaving many women more exposed due to the lockdown.\(^{75}\) Evidence of this has already

surfaced. For example, in Argentina the lockdown restrictions were directly linked to an increase in calls to the domestic violence hotline of 28 percent. Additionally, also in Argentina, women whose partners were also in quarantine were more likely to report an increase in interpersonal violence due to increased exposure to the perpetrator. 76 There also is evidence of this in India, where domestic violence complaints increased most in regions that implemented a more strict lockdown. 77

3.2.5 Older adults
The risk of adverse health effects from COVID-19 increases significantly with age and comorbidities, making the elderly especially vulnerable. Residing in a long-term care facility also substantially increases risk. For example, preliminary analysis of April 2020 COVID-19 exposure data in Italy indicated that 44 percent of infections during this period were contracted in nursing homes or homes for the disabled. 78 In the United States, as of mid-May 2020, nursing-home residents accounted for about one-third of COVID-19 fatalities. 79 While such findings are alarming, they probably underestimate actual infection and case fatality rates among older adults, since there is evidence that, especially at the beginning of national epidemics, deaths from COVID-19 went unrecorded in many long-term care facilities.

An immediate priority for countries fighting COVID-19 is to protect the elderly and those with significant comorbidities. Prevention, control, appropriate staffing, coordination, management, reporting, communication, and planning are all needed to safeguard older adults living in residential facilities. 80 In the longer run, the vulnerabilities revealed by COVID-19 point to the need to increase human capital resilience. This could mean rethinking policies and services for today’s elders, but also supporting younger generations to prepare for a healthy longevity in the future. This will involve stepping up prevention of noncommunicable diseases such as cardiovascular diseases, obesity, and diabetes, in conjunction with other strategies.

3.3 USING THE HCI TO SIMULATE THE IMPACT OF THE PANDEMIC

The HCI is designed to capture the human capital a child born today can expect to attain by age 18. Given that the future is uncertain, the best approximation of human capital accumulation for a child born today is based on the currently observed outcomes of older cohorts. While there is uncertainty about how long it will take for the world to arrive at a post-COVID-19 “new normal” (and what the world will look like then), for the purpose of the long-term outcomes captured by the HCI, the pandemic is mostly a transitory shock. For example, while school closures affect school-age children now, these are unlikely to affect children who are born today, assuming that the pandemic will be controlled and school will be in session by the time they are ready to start school.

However, the disruption to health systems and shocks to family income will affect young children’s survival and healthy development (stunting) now. In turn, this will affect their learning and schooling. Since all the data for the 2020 HCI were collected just before the virus struck, it serves as a pre-COVID-19 baseline, and the HCI construct

76 Perez-Vincent et al. (2020). The authors of the study also note a considerable increase in the number of calls related to psychological violence, by 57 percent.
77 Ravindran and Shah (2020).
79 See CDC (2020) and Yourish et al. (2020).
80 Such facilities include long-term care homes, residential care homes, nursing homes, welfare homes, and others.
can be used to simulate the direct and indirect impacts of the pandemic on young children’s human capital.\textsuperscript{81} Over time, it can be used to track the actual changes in human capital outcomes as the pandemic evolves.

The rest of this section discusses an example of a simulation of the effects of the pandemic shock on the future human capital of young children under 5 years of age. Then it uses the HCI to simulate how the pandemic—through school closures and shock to family income—will affect the future human capital of children who are currently in school.

3.3.1 Shock to children under 5

While COVID-19 is seemingly not as damaging to the health of children or pregnant mothers who are directly affected by it as previous pandemics,\textsuperscript{82} the COVID-19 economic shock is expected to be harmful for the youngest children and children in utero, because considerable drops in family income can lead to food insecurity, in turn leading to increased child mortality and stunting. An additional shock is the decrease in coverage of essential health interventions for pregnant mothers and young children. This decreased coverage is the direct result of disruptions to health systems due to the health workforce and supply chain issues. These shocks will affect child mortality and child health. Mapping them into changes in human capital as measured by the HCI requires estimates of how substantially mortality and stunting change in response to shocks to GDP per capita, as well as reductions in health services.

Since child health (captured by worsened stunting rates) and educational outcomes are closely intertwined, the shock is also expected to affect the amount of education this cohort of children will attain in the future as well as how much education they can retain. The calculation of the impact is developed formally in Annex 3B of this chapter.

Take a reduction in GDP per capita of 10 percent—a pessimistic scenario—with an elasticity of stunting to income of \( -0.6 \), this would imply an increase in stunting of 6 percent. For example, for a country like Bangladesh, where the stunting rate pre-COVID-19 was 31 percent, an income shock of this magnitude could increase stunting by 1.85 percentage points.\textsuperscript{83} Since children who are stunted are less likely to stay in school and learn, this increase in stunting could lead to a drop in expected years of school of 0.03 years, and a drop in harmonized test scores (HTSs) of 1.16 points.\textsuperscript{84} With about 10 years of schooling and an HTS of 370, the losses due to an increase in stunting could amount to nearly 1 percent of the HCI. Adding in the likely increase in child mortality due to health service disruptions and the income drop would further drive down the HCI by an additional 0.10 to 0.47 percentage points, depending on the assumptions. Altogether, a decline in income of 10 percent could lead to a decline in the HCI ranging from 1.18 to 1.50 percent. For a country like Bangladesh with an HCI score of 0.46, this would imply a decline to an HCI score of around 0.45.

Annex 3A to this chapter reports the methodology of the simulation in more detail. For each country, the percentage decline in income due to COVID-19 is estimated as the difference between projections of per capita GDP growth made in June 2020 and the pre-COVID-19 projections made in late 2019.

\textsuperscript{81} See appendix A for details on the methodology of the HCI.

\textsuperscript{82} Almond and Currie (2011). In early 1919, roughly one-third of all newborns had mothers who had been infected by influenza while pregnant. The 1918 pandemic was disproportionately deadly to those between 25 and 35 (Almond 2006).

\textsuperscript{83} Assuming an elasticity of \( -0.6 \), where a 10 percent drop in GDP per capita would increase stunting by 6 percent.

\textsuperscript{84} These calculations are based on the literature review in Galasso and Wagstaff (2019). The authors find that children who are stunted obtain 1.594 years less education, and score 0.625 standard deviations lower on standardized tests.
It then applies the calculations described above to simulate the likely effects on human capital as measured by the HCI for each country. Averaged across all countries, the projected shock would result in an HCI loss of 0.44 percent. This outcome is worse for low- and lower-middle-income countries (−0.73 and −0.64 percent, respectively), mostly because the stunting rates are highest for this group of countries (Table 3.1). While the loss may not seem large, it will likely set back children within the affected cohort for years to come, leading to accumulated losses. For example, the cohort of adults who were in utero during the 1918 influenza pandemic by 1960 had 0.1 less years of education than those adults born in the year before or after the pandemic. When comparing the wages of the same groups in 1960, those who were in utero had wages that were 2.2 percent lower than those of the neighboring cohorts. These losses build up over time and leave affected cohorts at a considerable disadvantage.

### 3.3.2 Schooling and learning
The human capital of the current cohort of school-age children is being heavily impacted by the pandemic through school closures: at its peak, nearly 1.6 billion children worldwide were out of school. The simulation framework proposed by Azevedo et al. (2020) quantifies the effects of this shock on the global stock of schooling and learning through three channels: during closures children lose out on opportunities to learn, they may forget what they have previously learned, and many may drop out due to income losses.

According to the 2020 HCI, pre-COVID the global average of the expected years of school is 11.2 years, which, when adjusted for learning, translated into 7.8 learning-adjusted years of school (LAYS). To simulate the effect of closures on learning, the simulation starts by assuming a value of learning gained in one year of schooling. This is proxied by harmonized test score (HTS) points per

---

85 For countries where stunting data are not available and thus not used in the calculation of the HCI, the income group’s average stunting rate is applied to the individual country to simulate the possible losses due to the pandemic.

87 This section was contributed by Joao Pedro de Azevedo based on Azevedo et al. (2020). The results presented in this section use the 2020 HCI numbers as baseline values. For that reason, they will be slightly different from those in the original paper.
year. To determine how much of this will be lost due to the closures, the simulation assumes three scenarios: optimistic, intermediate, and pessimistic, corresponding to 3, 5, and 7 months of school closures, respectively. The three scenarios also differ on the assumed effectiveness of the mitigation measures put in place by governments, which vary by income group. The three components are used to project HTS points lost due to school closures under the assumption that the losses due to school closures are not recuperated.

Expected years of school (EYS) are also projected to fall. This is because, due to the income shock, many children are likely to drop out of school. COVID-19 could lead an additional 6.8 million children to drop out of school around the world. Sixty percent of these dropouts will be children between 12 and 17 years of age, who are likely to leave school permanently because of losses in household income. The economic recession brought on by COVID-19, which is expected to shrink GDP per capita by 4 percent, is likely to increase the out-of-school population among global youth by 2 percent.

Take, for example, a country like Peru, which is an upper-middle-income country, and assume a drop in GDP per capita of 10 percent. The drop in GDP is likely to lead many kids to drop out of school, leading to a small loss in expected years of school (0.005). An additional loss to years of school is due to the closures and the limited capacity of countries to deliver education during school closures. Under the assumption that schools are closed for three months out of a 10-month school year, without any mitigation, students would lose 0.3 years of school. Assuming instead, in the optimistic scenario, a mitigation effectiveness of 0.4, only 60 percent of that period would be lost, leading to a loss of only 0.18 school years (0.3*(1-0.4)). A further dimension of loss comes from the drop in learning. Children in upper-middle-income countries like Peru gain 40 HTS points in a school year. With students missing out on 0.18 years of school, they are also losing 7.2 HTS points (40*0.3*(1-0.4)). Putting it all together means a loss of 0.27 learning-adjusted years of school.

Figure 3.2 depicts the combined losses in learning and expected years of schooling for different country income groups. Under the intermediate scenario of a five-month closure, COVID-19 could lead to a loss of 0.56 years of school, adjusted for quality. This means that school closures due to COVID-19 could bring the average learning that students achieve during their lifetime down to 7.3 learning-adjusted years of school. In the optimistic scenario, the projected loss is 0.25 years of schooling, and in the pessimistic scenario, 0.87 years.

Across the globe, the extent of this shortfall will vary. In high-income countries, where children were expected to complete 10.3 years of learning-adjusted schooling prior to the pandemic, the simulations suggest that COVID-19 could lower LAYS to 10.1 in the optimistic scenario and 9.2 in the pessimistic scenario. At the other end of the spectrum, children in low-income countries were expected to complete 4.3 years of learning-adjusted school prior

---

88 For high-income countries, the value is assumed to be 50 points in a year; 40 points for upper-middle-income countries; 30 points for lower-middle-income countries; and 20 points for low-income countries.
89 The authors assume that all governments offer some alternative learning modality. Estimates of their effectiveness are informed by existing multitopic household surveys. Thus, access and effectiveness of the implemented modalities differ by country income. Efficiency for lower-, lower-middle-, upper-middle-, and high-income countries under the pessimistic scenario is 5, 7, 10, and 15 percent, respectively. The values are doubled in the intermediate scenario and quadrupled under the optimistic scenario.
90 The authors use household surveys for 130 countries to calculate country-specific dropout income elasticities and welfare using cross-sectional variation by welfare quintiles. Refer to Azevedo et al. (2020) for details.
91 See Azevedo et al. (2020) for a detailed explanation on how the income shock is incorporated.
92 Intermediate scenario in Azevedo et al. (2020).
ACCUmUlATIoN INTERRUPTED? COVID-19 AND HUmAN C APITAl

The optimistic scenario suggests that this would fall to 4.1 years, while the more pessimistic scenario foresees a decline to 3.8 years.

Putting these losses in LAYS in the context of the HCI implies a drop in human capital for children of school age of 4.5 percent (Table 3.2).

What is known about the virus itself continues to evolve, so many behavioral patterns are difficult to predict. For instance, parental concerns about child and family safety will likely dominate household decision-making around sending children back to schools when they reopen. Hence, any estimates of dropouts that only consider...
the relationship between incomes and school dropouts are likely to underestimate the extent to which children’s schooling and learning will be affected by the pandemic. Additionally, these numbers ignore the possibility of remediating these losses.

### 3.3.3 The long-run HCI losses to the cohort

In 20 years, roughly 46 percent of the workforce in a typical country (people ages 20 to 65) will be composed of individuals who were either in school or under the age of 5 during the COVID-19 pandemic. Assume that the 2020 HCI summarizes well the human capital children under the age of 5 could have achieved, and that the 2010 HCI is the best representation of the human capital children who are currently in school could have achieved. With the HCI losses as calculated in the earlier sections, the HCI of the workforce in 20 years’ time in the typical country would be lower by almost 1 HCI point (0.01) due to COVID-19 today.

As an example, assume that a country’s HCI for children under 5 is expected to fall by 1 percent and that they represent 15 percent of the workforce in 2040. Also assume that the losses due to school closures are 4 percent and these children will be 30 percent of the workforce by 2040. If the HCI in 2010 for this country was 0.54 and in 2020 it is 0.56, then the HCI of that country’s workforce in 2040 will be 0.007 lower than it would have been in the absence of the pandemic.

Given that children who are currently in school will be a larger share of the workforce than those currently under 5, and that the losses for the former are larger in high-income countries, the fall is expected to be largest among high- and upper-middle-income countries, which are also the ones that have the highest levels of HCI and thus are projected to lose more (Table 3.3). The results shown here are meant to inspire action and show that without remediation, an entire generation could be left behind.

Notes: Calculations are based on the methodology presented in the Annex 3.A and 3.B. Projected GDP changes are from the June version of the Global Economic Prospects (GEP).

---

94 Roughly 34 percent of the workforce will be composed of individuals whose schooling was interrupted by the pandemic, and 12 percent of the workforce will be composed of individuals who were under the age of 5 during the pandemic.

95 To calculate the HCI loss by country, the percentage change for each of the cohorts (presented in Table 3.1 and Table 3.2) are applied to the HCI of 2020 for the under-5 cohort and the HCI of 2010 for the cohort of 2010 to arrive at an HCI value that is lost. Countries missing an HCI in 2010 were imputed the value of the country’s income group. The country’s projected population shares are used to calculate each country’s HCI point loss among the workforce. The result supposes that on average those who are currently between ages 18 and 45 will not experience any ill health effects due to the pandemic, and thus in 20 years their human capital will be the same.

96 $HC{I\ loss} = 0.56(-0.01)0.15 + 0.54(-0.04)0.3$. 
3.4 ANNEX 3A: COVID-19 SHOCK TO THE UNDER-5 COHORTS

The starting point for this simulation is a version of the HCI calculated with stunting only. Assuming that changes in stunting are sufficient to capture the health component of the index, through its relationship to height, and that the changes in adult survival rates due to the pandemic are unlikely to reflect the current health status of the current cohorts, the relevant HCI equation in log terms can be written as:

$$\ln(HCI) = \ln(Survival) + \phi \left( EYS \times \frac{HTS}{625} - 14 \right) + \gamma_{stunting}(\text{-stunting rate})$$

The changes in HCI for the under-5 cohorts are assumed to come from the income shock and reduction in health care access during the pandemic. Consequently, the pathways for the shock are as follows:

(1) The income shock affects under-5 mortality rates.
(2) The income shock also leads to an increase in stunting rates. In turn, a change in stunting rates is expected to be related to a change in the years of school completed by affected children. It is also likely to be related to a change in cognition, proxied by harmonized test scores.
(3) An additional shock is due to the reduced access to health services, be it due to fear of contagion or from the lockdown measures. This shock is expected to mostly affect under-5 mortality.

Therefore, the fall in access to health services and the income shock will both lead to an increase in child mortality and worsened stunting. Because more children will be stunted when they reach school age, it is also likely that this will decrease educational outcomes.

**Income shock**

The income shock ($\Delta y/y$) used in the simulations comes from the World Bank Global Economic Prospects. The values come from the difference between projected GDP per capita growth for 2020 utilized in the Macro Poverty Outlook from the World Bank Annual Meetings of 2019 (pre-COVID-19), and the GDP per capita growth projections made in June 2020.

**Stunting**

The effect of the income shock on stunting is:

$$\Delta \ln(HCI) = -\gamma_{stunting} \frac{\partial Stunting}{\partial y} \Delta y$$  \hspace{1cm} (1)

where $\gamma_{stunting} = 10.2 \times 0.034 = 0.35$ as discussed in Appendix A. Although a direct value of $\frac{\partial Stunting}{\partial y}$ is not available, this is replaced with an elasticity from Ruel et al. (2013):

$$\frac{\partial Stunting}{\partial y} = -0.6$$  \hspace{1cm} (2)

Inserting (2) into (1) yields the following expression for the direct effect of an income-induced increase in stunting on the HCI:

$$\Delta \ln(HCI) = -\gamma_{stunting} \frac{\partial Stunting}{\partial y} \frac{y}{Stunting} \Delta y$$  \hspace{1cm} (3)

For countries missing stunting data, the average rate for its income group is applied.

---

97 Because the parameter $\gamma_{stunting}$ embodies the best alternative of the link between stunting to adult height and from adult height to earnings, the index can be expressed by relying just on stunting as a proxy for health.

98 World Bank (2020).
**Education**

The effect of the income shock on education of a child born today is expected to come through the effect on stunting:

\[
\Delta \ln HCI = \frac{\phi}{625} \left( \frac{\partial EYS}{\partial y} \cdot \frac{\partial HTS}{\partial Stunt} \cdot HTS + \frac{\partial HTS}{\partial Stunt} \cdot \frac{EYS}{\partial y} \right) \Delta y \tag{4}
\]

where \( \phi = 0.08 \) and \( \frac{\partial EYS}{\partial Stunt} = -1.594 \) years of education, and \( \frac{\partial HTS}{\partial Stunt} = -0.625 \) SD. Inserting (2) into (4) gives us the effect of the income shock on education, operating through increased stunting:

\[
\Delta \ln HCI = \frac{\phi}{625} \left( \frac{\partial EYS}{\partial Stunt} \cdot \frac{\partial HTS}{\partial Stunt} \cdot HTS + \frac{\partial HTS}{\partial Stunt} \cdot \frac{EYS}{\partial y} \cdot \Delta y \right) \tag{5}
\]

**Mortality**

The negative income shock increases child mortality, with the following effect on the HCI:

\[
\Delta \ln HCI = \frac{\partial \ln \text{survival}}{\partial U5MR} \cdot \frac{\partial U5MR}{\partial y} \cdot \Delta y \tag{6}
\]

where \( \frac{\partial \ln \text{survival}}{\partial U5MR} \) is equal to \( -\frac{1}{1 - \text{U5MR}} \). Although a direct value of \( \frac{\partial U5MR}{\partial y} \) is not available, this is replaced with a semielasticity from Ma et al. (2020):

\[
\frac{\partial U5MR}{\partial y} = -0.013 \tag{7}
\]

Inserting (7) into (6) yields:

\[
\Delta \ln HCI = \frac{\partial \ln \text{survival}}{\partial U5MR} \cdot \frac{\partial U5MR}{\partial y} \cdot \Delta y \tag{8}
\]

An additional shock to mortality is assumed to come from the change in access to health services measured in months of disrupted access:

\[
\Delta \ln HCI = \frac{\partial \ln \text{survival}}{\partial U5MR} \cdot \frac{\partial U5MR}{\partial access} \cdot \Delta access \tag{9}
\]

Although a direct value of \( \frac{\partial U5MR}{\partial access} \) is not available, this is replaced with a monthly access change to the elasticity of the under-5 mortality rate from Roberton et al. (2020):

\[
\frac{\partial U5MR}{\partial access} = 0.136 \tag{10}
\]

This value suggests a monthly relative increase in under-5 mortality of 13.6 percent given a one-month lack of access. Since the values that enter the index are annual, this is extrapolated to the year and inserted into (9):

\[
\Delta \ln HCI = \frac{\partial \ln \text{survival}}{\partial U5MR} \cdot \frac{\partial U5MR}{\partial access} \cdot \Delta access \cdot \text{U5MR} \tag{11}
\]

Under the baseline scenario, a change in the access to care of three months is assumed, thus in (11), access is equal to 12 months and \( \Delta access \) is equal to 3 months.

---

**Notes:**

99 The elasticities are disaggregated by income groups: for high income countries it is assumed to be 0; for upper middle income equal to -0.008; for lower middle income equal to -0.01; for lower income equal to -0.013. Ma et al. (2020) express these values as a 1 percent decrease in GDP per capita being associated with an increase of 0.13 under-5 deaths per 1000 children. Or an increase of 0.013 percentage points in under 5 mortality rates.

100 Roberton et al. (2020) offer three scenarios where the effect ranges from 8 to 34.5 percent.
Putting all these pieces together gives us the total in HCI change due to the pandemic:

\[ \Delta \ln HCI = \frac{\partial \ln \text{survival}}{\partial \text{USMR} \frac{\partial \text{USMR}}{\partial \text{access}} \frac{\partial \text{access}}{\partial \text{U5MR}}} + \frac{\partial \ln \text{survival}}{\partial \text{USMR} \frac{\partial \text{USMR}}{\partial \text{y}} \frac{\partial \text{y}}{\partial \text{Stunting}}} + \phi \frac{\partial \text{EYS}}{\partial \text{Stunting}} \frac{\partial \text{Stunting}}{\partial \text{y}} \frac{\partial \text{y}}{\partial \text{Stunting}} \]

Note how the first component, the one related to access, enters independently from the income shock.

### 3.5 ANNEX 3B: COVID-19 SHOCK TO SCHOOL AGE COHORTS

The shock to children who are presently in school is derived as in Azevedo et al. (2020), but using the data for the 2020 HCI. The shock to children operates through two channels: (a) the income channel, leading to increased dropouts, and (b) the school closure channel, leading to loss in learning and in school years. Recall that learning-adjusted years of school (LAYS) at pre-COVID-19 baseline (0) is:

\[ \text{LAY}_S^0 = \text{EYS}_S^0 \times \frac{\text{HTS}_S^0}{625} \]

The changes in income, how well governments can deliver education while schools are closed, and how long schools are closed are all expected to decrease LAYS. The number of out-of-school children is assumed to increase due to the income shock. These changes are calculated for each welfare quintile using data from 130 household surveys using the latest available Global Monitoring Database (GMD), separately for children ages 4 to 11 and 12 to 17. The shock from the GDP per capita growth projections is used to arrive at a new welfare value. This is achieved by assuming the shock is uniform across the distribution; thus the shape of the distribution is maintained, it is just shifted to the left. The shift of the household welfare of children moves children across welfare quintiles; the quintile thresholds are the same as those from the original welfare distribution. Finally, the quintile’s share of out-of-school children is used to get the new total number of out-of-school children. In essence, when household income drops, children move down the welfare quintiles (because the thresholds are maintained). With more children in lower welfare quintiles with higher shares of out-of-school children, there will be an overall increase in the share of out-of-school children, since the denominator (total number of children in the specific school age bracket) stays the same.

The first component of the change in LAYS is the share of students who drop out due to the income shock (D).

When children go to school, they experience in-person learning, which is assumed to be the most efficient learning mode. With school closures, children will experience different, less efficient, learning. The length of school closures differs according to scenarios that range between 3 and 7 months (Table 3.4). The effectiveness of different remote learning strategies deployed, and the scenarios, are linked to the country’s income group (see Table 3.5).

---

101 For countries without a household survey, the overall change in out-of-school rates for the country’s income group is used.

</table>

The second component of the change in $LAYS$ is the share of the school year that is lost due to the closure and to the alternative learning modality ($S$):

$$S = (1 - \text{mitigation}) \times \text{closure share of school year}$$

Harmonized test scores are assumed to change over a school year by a certain amount ($p$); the amount is dependent on the country’s income group (see Table 3.6). The learning of these children is compromised due to the closures and the limited effectiveness of the deployed learning modality.

</tr>
</tbody>
</table>

The final component to the change in $LAYS$ is the amount of learning that takes place under the remote learning scenario ($H$):

$$H = S \times p$$

The change in $LAYS$ is then:

$$\Delta LAYS = LAY S_1 - LAY S_0$$

$$\Delta LAYS = LAY S_1 - EYS_0 \times \frac{HT S_0}{625}$$

where $LAYS_1$ is equal to:

$$LAYS_1 = \left( EYS_0 - S - D \right) \frac{(HT S_0 - H)}{625}$$
4 Utilizing Human Capital
The World Bank’s Human Capital Index (HCI) captures the size of the income gains when today’s better-educated and healthier children become tomorrow’s more productive workers. Specifically, a child born today can expect to be \( \times 100\% \) as productive as a future worker as she would be if she enjoyed complete education and full health. But this implicitly assumes that when today’s child becomes a future worker, she will be able to find a job—which may not be the case in countries with low employment rates. Moreover, even if today’s child is able to find employment in the future, she may not be in a job where she can fully use her skills and cognitive abilities to increase her productivity. In these cases, human capital can be considered underutilized, because it is not being used to increase productivity to the extent it could be. For example, unemployed future workers may be underutilizing their human capital, as are those out of the labor force. Likewise, engineers driving taxis are underutilizing their human capital because, even though they are employed, they do not hold jobs in which their education increases their productivity.

In addition, a gender gap—which is not apparent in the human capital dimensions captured by the HCI—emerges and deepens during the working years. In many countries, women face worse jobs and income opportunities compared to men, even with the same human capital. As such, simply considering the HCI by sex may give a partial view in terms of realizing the potential of human capital investments.

This chapter introduces two Utilization-Adjusted Human Capital Indices (UHCIs) that, as their name suggests, adjust the HCI for labor-market underutilization of human capital. The UHCIs are designed to complement the main HCI, and not to replace it. In part, this is because these two measures have different purposes: the HCI is an index of the supply of a factor of production (in the future), whereas the UHCIs are a hybrid between an index of factor supply (capturing investment in human capital), and a utilization index (capturing how efficiently that human capital is used in production). Moreover, there are numerous challenges in defining and measuring utilization in a consistent way across diverse country contexts. As such, the UHCIs should be viewed as a first attempt to address utilization in a simple way consistently across countries, and should be applied with caution in policy analysis.

Importantly, the HCI and UHCI only measure the effect of human capital on labor-market earnings and future GDP per capita. But this is only one benefit of human capital. In many other domains, human capital improves wellbeing and economic development. More-educated parents have children with better human capital outcomes, and women with more human capital are more empowered. Even outside the categories of “better employment” considered below, human capital can still increase productivity—for example, smallholder farmers might use fertilizer more efficiently—but just the increase is less dramatic than for other employment types. As such,

---

1 Prepared by Steven Pennings (spennings@worldbank.org) with helpful comments from Roberta Gatti, Aart Kraay, Michael Weber, Kathleen Beegle, Paul Corral, and David Weil, as well as from other internal, and external reviewers. See Pennings (2020) for an in-depth treatment.
incomplete utilization should not be interpreted as there being no gains from human capital investments, but rather that private labor market gains are smaller than they could be.

The two UHCIs take different approaches to measuring utilization. In the basic UHCI, utilization is measured as the fraction of the working-age population that is employed. While this measure is simple and intuitive, it is not able to capture underutilization resulting from a mismatch between the skills and cognitive abilities required to do a job, and the skills and cognitive abilities of the people employed to do it. The full UHCI measure adjusts for this mismatch by introducing the concept of “better employment,” which includes the types of jobs that are common in high-productivity countries.

Despite different methodologies, the basic and full measures produce broadly similar utilization rates. Utilization rates are U-shaped in per capita income across countries, first declining with income at lower income levels and then rising at higher income levels. This feature of utilization rates implies that UHCIs are low in the poorest countries where the HCI is also low on average, but remain low over a wider range of lower middle-income countries where rising HCIs are offset by declining utilization.

Moreover, both UHCIs reveal starkly different gender gaps from those using the HCI. Girls have a slight advantage over boys in human capital early in life, resulting in a higher HCI for girls on average. But female utilization rates are typically lower than those for males, resulting in lower UHCIs. While gender gaps in human capital in childhood and adolescence (especially education) have closed in the last two decades, large challenges remain to these investments being realized in terms of income opportunities for women.

4.1 METHODOLOGY AND THE BASIC UHCI MEASURE

Both the basic and full UHCIs have a simple form, as the utilization rate multiplied by the HCI:

\[ UHCI = \text{Utilization Rate} \times \ HCI \]

For the basic UHCI, this multiplicative form stems from its connection to economic growth. In the long run, GDP is proportional to the number of workers (employment) multiplied by the productivity boost that each worker gets from their human capital. The basic UHCI inherits this multiplicative form, where the HCI captures the productivity boost from human capital, and the utilization rate captures employment.

The HCI is derived to measure the effect of human capital on future GDP per capita so that projected future per capita GDP will be approximately \(1/HCI\) times higher in a “complete education and full health” scenario than in a ‘status quo’ scenario. This definition implicitly assumes that utilization rates of human capital—such as employment prospects—are the same in the ‘complete education and full health’ scenario as in the status quo scenario.

Both UHCI measures are derived in a similar way, in keeping with the economic interpretation of the HCI. However, for the UHCIs, utilization rates are now different in the status quo and full human capital scenarios. Specifically, both UHCI indices are derived as future GDP per capita under the status quo relative to future GDP per capita with complete health, education, and full utilization (Equation 2).

---

2 See box 4.1 for a derivation. More specifically, this requires a Cobb-Douglas production function, and the assumption that the capital-to-output ratio is constant in the long run (one of Kaldor’s facts).

3 In the full UHCI, the utilization rate is defined as UHCI/HCI—and so satisfies Equation (1) by construction—but still turns out to have an intuitive interpretation (see Section 4.3).

This means that, in the long run, GDP per capita will be \(1/UHCI\) times higher in a world of full utilization, full health, and complete education than in the status quo.\(^5\)

\[
(2) \quad \text{UHCI} = \frac{\text{future GDP per capita (status quo)}}{\text{future GDP per capita (full utilization, full health, complete education)}}
\]

For the basic UHCI, the utilization rate is simply the employment rate of the working-age population. This is current employment \(L\), relative to a measure of potential employment under “full utilization” \(L^*\), the maximum theoretical employment. The standard definition of the potential labor force is the working-age population 15–64 years old. This definition is also adopted for \(L^*\).\(^6\) Employment \(L\) is defined as the number of people 15–64 years old that are in paid employment (or are self-employed) to be consistent with the definition of the potential labor force.

As mentioned above, the basic UHCI takes the simple multiplicative form in Equation (1) because, in a standard production function, long-run GDP per capita is proportional to human capital per worker \(h\) multiplied by employment \(L\) per capita (see Box 4.1 for a derivation). Future GDP per capita under the status quo (in the numerator of Equation 2) is proportional to \(hl\), and future GDP per capita under complete utilization and complete human capital is proportional to \(h^*L^*\) (\(h^*\) is complete human capital per worker) in the denominator of Equation (2). Because the proportionality factors are the same, and so cancel out, this can be rearranged as \(\text{HCI} = \frac{h}{h^*} \times \text{multiplied by the basic utilization rate} \quad \text{Util (basic)} = \frac{L}{L^*}\).

A natural concern is that in countries with low basic utilization rates, human capital, as measured by the HCI, will have less effect on economic growth. However, this is not the case.\(^7\) In the framework of the basic UHCI, an increase in human capital alone has the exact same effect on long run economic growth as in the HCI, but it’s just that countries can do better by also increasing utilization (it is not one or the other).\(^8\)

The main data source for the basic utilization measure is “Employment-to-population by sex and age (\(\%\)) – Annual,” Age (Youth, Adults): 15–64, from the International Labour Organization (ILO), using the latest period available.\(^9\) The secondary data source is the World Bank’s Global Jobs Indicators (JOIN) Database, which has employment based on the same population age group, with a sample skewed towards low- and middle-income countries. Data is generally taken from the most recent source if both are available.\(^10\) The median year of the data is 2017, with 95 percent of countries having data from the 2010s. The basic utilization measure is available for 185 countries. The measurement of the full UHCI is discussed in Section 4.3.

### 4.2 THE BASIC UTILIZATION-ADJUSTED HCI IN THE DATA

Basic utilization rates are not strongly correlated with the HCI (correlation coefficient of 0.45), which means that countries’ UHCI scores will differ from those in the HCI (Figure 4.1). Employment rates average around 0.6, which suggests that the UHCI will, on average, be around 60 percent of the value

---

5 Just like the HCI, the UHCI can also be interpreted in terms of productivity: a child born today can expect to be only UHCI\times100\% as productive as she would be, on average, if she enjoyed complete education and full health, and her future labor was fully utilized.

6 Naturally, no countries will have employment rates of 1. But this is consistent with the approach in the HCI, where no country has perfect test scores or 14 expected years of schooling.

7 In the full UHCI, discussed in Sections 4.3-4.4, countries with very low “better employment” ratios will have GDP that is less sensitive to increases in human capital. But even there, improvements in human capital will still increase growth.

8 Technically, this is because the implicit assumption in the HCI is that basic utilization rates are constant across status quo and full human capital scenarios. A full employment assumption is not required.

9 Downloaded from https://www.ilo.org/shinyapps/bulkexplorer7/ on 13 December 2019.

10 In some cases, the more recent data source of employment data is not used if it is missing data for the full UHCI.
of the HCI (Figure 4.2), though this varies substantially across countries.

Employment rates (basic utilization) are approximately U-shaped in log per capita income (Figure 4.3). High-income countries have the highest utilization rates (around 0.7 for the group as a whole). This is unsurprising, as it is difficult to have high per capita incomes with few people working. Low-income countries have utilization rates of around 0.6 on average, though many low-income countries also have extremely high employment rates of around 0.8—like Madagascar (MDG), Burundi (BDI), and Mozambique (MOZ). High employment rates among low-income countries are likely because most people are so poor that they need to work outside the home to survive. At around 0.55, lower-middle-income countries have the lowest utilization rates, mostly because slightly higher incomes make it feasible for people (especially women) not to work outside the home (see Section 4.7 for a discussion of utilization rates by gender).

Employment rates vary widely among low- and middle-income countries. While many low-income countries have high employment rates of around 0.8, others have employment rates of around 0.4—including Malawi (MWI), Nepal (NPL), and Afghanistan (AFG). In part, this may reflect the 2013 change in the ILO definition of

---

**Box 4.1: Deriving the basic UHCI**

Future GDP per capita of the next generation \( (y) \) in the status quo world is given by a Cobb-Douglas production function:

\[
y = A K^{1-\beta}(hL)^{\beta}/N \tag{1}
\]

where \( h \) represents human capital per worker under current policies, and \( L \) represents the number of workers under status quo employment rates. \( A \) is TFP, \( K \) is the amount of physical capital, and \( N \) is the future population. TFP and the future population are assumed to grow at the same trends in all scenarios.

In an alternative world, there is complete human capital per worker, denoted \( h^* \), and complete employment of potential workers, denoted \( L^* \). Long-run GDP per capita in this complete human capital-complete employment world is denoted \( y^* \). As in Kraay (2018), the production function can be rearranged so that the physical capital-to-output ratio \( K/Y \) is constant in the long run. Then, future GDP per capita under the status quo relative to the complete human capital, complete utilization scenario is given by:

\[
\frac{y}{y^*} = \frac{A^{1/\beta}(K/Y)^{(1-\beta)/\beta}}{A^{1/\beta}(K/Y)^{(1-\beta)/\beta}} \frac{h L/N}{h^* L^*/N} \tag{2}
\]

\[
= \frac{1}{L} \times \frac{h}{h^*}
\]

\[
= Utilization \ (basic) \times HCI
\]

\[
= UHCI \ (basic)
\]
In Malawi, a household survey in 2005 reported employment rates of 0.8, twice the most recent figure (from 2017). Likewise, in Nepal a household survey in 2008 reported employment rates of 0.84, also around twice the most recent figure (also from 2017). The difference is likely due to exclusion of own-use production workers in 2017, though this is not well documented.

These measurement issues also motivate using a more specific definition of employment in the full UHCI (discussed in the next section).

Notes: Based on 169 countries with data available. Nicaragua and Nepal are highlighted in red. For Figure 4.2: Dashed line is 45 degree diagonal, and solid line is a fitted model where y = -0.14 + 0.88x

Figure 4.3: Employment-to-Population (basic utilization) and GNIPC

| Source: World Bank calculations based on the World Development Indicators, the International Labour Organization and the Global Jobs Indicators Database. |
| Notes: Based on 182 countries with data available. Working-age population is 15-64. |

To understand the implications of differences between the UHCI and HCI for long-run economic growth, consider the example of two countries, Nicaragua (NIC) and Nepal (NPL). These countries have similar scores for the HCI (0.5), but very different employment rates (Figure 4.1, dark red dots). The employment rate in Nicaragua is around 0.65, which is above the median, as against that in Nepal, 0.37, which is around the 5th percentile. This means that the basic UHCI score of Nepal (0.18) is much lower than that of Nicaragua (0.33) (Figure 4.2, dark red dots). As mentioned above, the increase in long-run per capita income moving to full human capital is 1/HCI times that in the
status quo, and long-run per capita income moving to full human capital and complete utilization is 1/UHCI that in the status quo. An HCI score of 0.5 for both countries implies that long-run per capita incomes would double moving to full human capital. However, moving to full human capital and full utilization of that human capital results in long-run GDP per capita that is 3 times the status quo in Nicaragua, but 5.4 times the status quo in Nepal.\(^{13}\)

The basic UHCI is fairly flat over a wide range of log income before increasing (Figure 4.4). Specifically, the UHCI is almost flat moving from low income (0.23) to lower-middle income (0.26), as higher HCI scores are largely offset by lower utilization rates. But then the UHCI increases rapidly to upper-middle income (0.32) and high income (0.51), as both human capital and utilization rates increase together.

### 4.3 THE FULL UTILIZATION-ADJUSTED HCI

One conceptual issue with the basic utilization measure (employment rate) is that it assumes that all jobs are the same in terms of their ability to utilize human capital. But in practice, a large share of employment in developing countries is in jobs where workers cannot fully use their human capital. For example, in the poorest countries, around half of all workers work on family farms or as agricultural day laborers, where productivity is low (Merotto et al. 2018). For the rest, around two-thirds of non-agricultural workers are self-employed or unpaid in family businesses. These include many small-scale traders selling household goods or food, where the majority of time is spent waiting for customers.

While there is scope for human capital to increase productivity in these jobs, it is more limited. Filmer and Fox (2014) compare the income of household enterprise owners of different education levels in four African countries. On average, the increase in income due to education, while positive, is much less than would be predicted given the number of years of schooling.\(^{14}\) Most developing countries suffer from high rates of mismatch between the level of education required for a job, and the education of the people doing it: the well-known anecdote of unemployed engineers driving taxis.\(^{15}\) In the literature, this is often referred to as “over-education”, though a more appropriate description is “underutilization” as it is the lack of jobs and not the level of education that is the cause of the mismatch. In some regions, especially the Middle East and North Africa, underutilization is often associated with self-employment, for example, while queuing for a formal sector job.\(^{16}\)

To address this, the full UHCI introduces a concept of better employment, which is designed to capture the employment categories where people can better use their human capital (subject to available data). More specifically, better employment is defined as non-agricultural employees, plus employers. This definition is not intended as a value judgment, but rather is based on the types of jobs that are relatively rare in low-income countries, but are common in high-income countries—suggesting they are associated with higher productivity. The share

---

\(^{13}\) For the average low-income country, long-run incomes in the complete utilization and human capital scenario would be around 4.5 times those of the status quo (1/0.22 = 4.5), compared with 2.5 times that with complete human capital alone (1/0.4 = 2.5).

\(^{14}\) On average, those with a complete secondary education were only earning 60 percent more than those with no education, which is the equivalent of less than six years with an 8 percent return to education. Omitted variables such as parental income and ability mean that the six years is likely an overstatement.

\(^{15}\) See Battu and Bender (2020) for a survey. Another cause of the mismatch can be poor education quality, where those with a qualification aren’t able to perform the functions required. In this case, the cause of the engineer driving a taxi is because he or she is not able to perform the tasks of an engineer due to poor quality education. Handel et al. (2016) find that in 12 low- and middle-income countries, the overeducation/underutilization rate is 36 percent. Overeducation/underutilization rates vary across countries and can depend on how it is measured.

\(^{16}\) Handel et al. (2016) and Gatti et al. (2013).
of employment in better jobs increases from about 20 percent in low-income countries to 80 percent in high-income countries (Merotto et al. 2018). The main categories excluded from the definition are subsistence own-account/family agriculture, small-scale traders, and landless agricultural laborers, as these employment types are only common in low-income countries—suggesting they are more likely to have lower productivity. By using a more specific definition of employment, the full UHCI also avoids variation in utilization rates caused by differences in the definition of employment that affected the basic UHCI.

The definition of better employment is based on the way that the work is organized, rather than whether the job is formal or informal. For example, non-agricultural employees could be formal or informal. Better employment involves work organized in a team consisting of at least an employer and an employee, where employees are paid for their work (rather than out of familial obligation). This allows a minimum degree of specialization and organization, which helps to boost productivity and allows for people to use their skills.

A second conceptual issue with the basic measure is that utilization should be relative to potential, which will depend on how much human capital there is to underutilize. That is, a doctor working as an agricultural laborer results in severely underutilized human capital, whereas the human capital of a worker with no education doing the same job is closer to being fully utilized. This means the utilization scores of countries with higher levels of human capital should be more heavily penalized by a lack of better employment.

Putting these concerns together suggests that the full UHCI should depend on the better employment rate (BER) (as a share of the working-age population), rather than the raw employment rate. However, the full utilization rate is not simply the BER, because this fails to adjust for how much human capital there is to underutilize if people are not in jobs where they can fully use the human capital. Instead, utilization rates for those without better jobs should depend inversely on the HCI (relative to a natural minimum). The full utilization measure captures both concerns. The full UHCI is a weighted average of the country’s HCI (for those in better employment), and the minimum HCI (for the rest) and is described further in Box 4.2 (and Equations 3 and 4). The full UHCI can also be derived based on the increase in long-run GDP per capita moving from the status quo to a world with full human capital and full utilization in better employment (see Pennings, 2020).

In terms of data, the BER is constructed as the employment rate (as in basic utilization measure), multiplied by the share of employment in better jobs (SEBJ). The measurement of the SEBJ requires data on the number of employers, non-agricultural employees, and total employment. The primary source is the ILO series “Employment by

---

17 The definition of formal employment varies across countries, but it generally refers to the coverage of the worker with respect to benefits like unemployment insurance, pensions, sick leave or annual leave.

18 Better employment differs from “decent work” (ILO) and “good jobs for development” (World Bank 2012).

19 A final technical issue is that some of the increase in GDP in the basic UHCI comes from utilizing people’s time, rather than utilizing their human capital. The full UHCI also addresses this concern (see Pennings, 2020).

20 It is important to acknowledge that the definition of better employment and the full UHCI are stylized for simplicity and cross-country data availability. In reality, many people without better jobs can partially use their human capital to increase productivity beyond that of raw labor. For example, education is positively correlated with high-yield-variety seed choice among Indian farmers (Foster and Rosenzweig, 2010). Moreover, healthier people may be more productive laborers. Assuming that only educational human capital (not health human capital) is underutilized outside better employment results in the same U-shape pattern in per capita GNI, but with higher utilization rates (and UHCI) for low-income countries (not reported). Moreover, there are many examples of people without better jobs using their human capital to its full extent, such as self-employed professionals. However, the availability of cross-country employment data limits the amount of nuance possible in this regard.
Box 4.2: Definition of the full UHCI

The full utilization measure is a weighted average of the utilization rates of those in better employment, and the utilization rate of the rest of the working-age population. Workers in better employment are assumed to be as productive as their human capital allows—their human capital is fully utilized (utilization rate of 1). All others, a fraction (1- BER) of the working-age population, are assumed to be only as productive as “raw” labor, and hence any excess human capital is underutilized.

In the HCI, “raw labor” has productivity of $HCI_{\text{min}} = 0.2$. This is the productivity of a worker with zero years of schooling, and the worst possible health outcomes.\(^a\) In contrast, the potential productivity of a worker if they were in better employment is just $HCI$. Hence the worker’s productivity relative to potential, or utilization rate, is $HCI_{\text{min}}/HCI$. For example, in a country with HCI=0.4, workers without better employment will be half as productive as they could be if they were in better employment (0.2/0.4), and so their utilization rate is 0.5. This means that a shortage of better employment leads to more severe underutilization in countries with more human capital. The full utilization measure is given by:

\[
\text{Utilization (full measure)} = BER \times 1 + (1 - BER) \times \frac{HCI_{\text{min}}}{HCI}
\]

The full UHCI is the full utilization measure multiplied by the HCI, as in Equation (1). This means that the full UHCI is a weighted average of the HCI (for the share of the population in better employment) and the minimum HCI (for the rest of the working-age population):

\[
\text{UHCI (full measure)} = BER \times HCI + (1 - BER) \times HCI_{\text{min}}
\]

\(^a\) The minimum HCI score is derived by assuming zero years of schooling, complete stunting, and zero chance of adults surviving to age 60. $HCI_{\text{min}} = 1 \times e^{0.08 \times (0-14)} \times e^{0.65 \times (0-1) + 0.35 \times (0-1)} / 2 \approx 0.2$. See Kraay (2018), equations 9-12. The probability of survival to age 5 is assumed to be 1, as this doesn’t affect the growth calculations.

---

sex, status in employment, and economic activity (Thousands),” using the most recent year available.\(^21\) The secondary source is the JOIN database. At the time of writing, the public JOIN dataset provides a split by status in employment or economic activity, not both, so the SEBJ is calculated using an unpublished version constructed from the underlying microdata. The most recent data source is used if both the ILO data and JOIN are available. For many countries, there are missing data on the number of agricultural employees. In these cases, the number of agricultural employees is interpolated using ILO data on total agricultural employment (which is more widely available). The full utilization measure is available for 161 countries.

4.4 FULL UTILIZATION-ADJUSTED HCI IN THE DATA

The full utilization measure has the same U shape in log per capita income as the basic utilization measure, and similar mean values overall (0.62) and for each income level, though with less

\(^21\) Downloaded from the ILOSTAT website on 20 February 2020 (defined using ICSE-93).
dispersion (Figure 4.5). However, the U-shaped pattern has quite different causes from those driving the basic utilization measure. For the full measure, the highest-income countries have around 70 percent of the working-age population in better employment, (Figure 4.9) which drives the high utilization rate. For low-income countries, only around 10 percent of the working-age population are in better employment, so the utilization rate for these countries is mostly determined by how much human capital there is to underutilize.

In the ten lowest-income countries, the HCI ≈ 1/3, so $HC_{\text{min}} / HCI$ is around 0.2/0.33 = 0.6—close to the full utilization rate for those countries in Figure 4.5. The full utilization rate falls from low-income to middle-income countries, as higher rates of human capital mean that there is more human capital to underutilize (and the BER only increases slightly).

The full UHCI also has the same shape in per capita income as the basic UHCI (and similar mean values for each income level, Figure 4.6). However, for the lowest-income countries, the UHCI value converges almost exactly to 0.2, with little variation (as against wide variation in the basic UHCI). The reason is that 0.2 is the minimum HCI score, which is the assumed productivity of “raw labor” for those without better employment.

4.5 COMPARING THE UTILIZATION MEASURES

While the full and basic utilization measures have the same U-shaped relationship with per capita income, they often differ substantially for individual countries (Figure 4.7, correlation of only 0.6). The strongest correlation is for high income

---

22 This is driven by a number of countries on the left side of Figure 4.7 in MENA and elsewhere where a high fraction of total employment is classified as better employment (such as wage employment), and a number of countries, often in EAP, with lower rates of wage employment on the right side of Figure 4.7. Some of these EAP countries are also penalized in the full measure by having a high HCI that increases the potential to underutilize human capital.
countries, because in order to generate high per capita incomes, employment rates need to be high and those people working need to be productive. But for lower income countries, the drivers of high utilization vary across measures, and the similarity of average scores is coincidental. Specifically, employment rates (basic utilization) are often high in low-income countries because people cannot afford not to work, though with a lot of variation due to the inconsistent cross-country classification of work in subsistence agriculture. In contrast, there is little variation in full utilization rates across low-income countries, because low-income countries have little human capital to underutilize.

For the UHCI, the scores of individual countries are very similar in the full and basic measures (Figure 4.8, correlation 0.93). In part this is because full and basic UHCI have the HCI as a common component. It is also because the differences between the two utilization measures occur mostly for countries with a low HCI, which mechanically shrinks any differences in utilization rates when forming the UHCI.\textsuperscript{23}

4.6 DISAGGREGATION BY REGION

Regions line up similarly according to the UHCI and to the HCI (Figure 4.10), though UHCI scores are lower. Sub-Saharan Africa (SSA) has the lowest HCI (of around 0.4), and also the lowest UHCIs (of around 0.23). South Asia has similar UHCI, but higher HCI (reflecting slightly lower utilization rates). Latin America and the Caribbean (LAC) and the Middle East and North Africa (MENA) are next, with HCI scores around 0.56 and UHCI scores around 0.35, though MENA does relatively better for the full UHCI than the basic UHCI, reflecting higher rates of wage employment. East Asia and the Pacific (EAP) are marginally higher, followed by Europe and Central Asia (ECA).

\textsuperscript{23} The one exception is Vietnam, which has high employment rates, but a low fraction of that is in better jobs. These differences remain prominent in the full UHCI because of Vietnam’s high HCI score.
Many of the trends above are driven by differences in utilization rates by gender. While the HCI is roughly equal across genders with a slight advantage for females relative to males, female utilization rates are typically lower than those for males (Figure 4.11 and Figure 4.12, Figure 4.13 and Figure 4.14) leading the UHCI also to be lower for females than males (Figure 4.15 and Figure 4.16, Figure 4.17 and Figure 4.18). Male and female UHCI increase proportionately, but with a constant gap for females (implying a larger gap for males).
The gender gap is larger for the basic measure than the full measure. Surprisingly, when women join the labor force, they more rapidly move into better employment.²⁴ More generally, female employment rates are strongly U-shaped in the level of income, whereas male employment rates are much flatter.²⁵ The largest gaps in utilization rates across genders (for both

²⁴ See Pennings (2020), Figure 25A.
²⁵ See Goldin (1995). Klasen (2019) shows that the U-shaped pattern of female employment rates is mostly due to region fixed effects, and not the development path for an individual country.

Notes: Based on 138 countries (Figure 4.13) or 141 Countries (Figure 4.14) with available data.

measures) are for several oil/gas producers: Bahrain, Kuwait, Oman, Qatar and Saudi Arabia. These countries have very high male employment rates—almost all of which is in wage employment (perhaps due to migrant workers)—but low or average female utilization rates.

Figures 4.19 and 4.20 break down the HCI and UHCIs by gender and region. In almost all regions, the female HCI is higher than male HCI (equal for South Asia). However, the opposite is true for the UHCI: in almost all regions the female UHCI is lower (the only exception is ECA for full UHCI).
The largest gender gaps for the basic UHCI are in MENA and South Asia. In these two regions the female basic UHCI is very low, reflecting low employment rates driven by a variety of factors, including social norms. However, the full UHCI has smaller gender gaps, in part because of small gaps in how much human capital there is to underutilize.

---

26 More specifically, female labor force participation rates in MENA are low for women without tertiary education, whereas those rates are much higher for women with tertiary education (Gatti et al 2013). This may reflect high reservation wages, and because tertiary education is required for public-sector jobs that are perceived to be safer for women.
**Figure 4.19: Gender Gaps by Region**

**Box 4.3: Closing gender gaps in human capital outcomes: Where do we go from here?**

The HCI approach implicitly assumes that human capital investments translate into productivity through labor market opportunities. However, there is considerable variation in how human capital is utilized in terms of paid work and labor markets. In particular, considerable and well-documented gaps exist in labor market opportunities between men and women. Globally, only 1 in 2 women participate in the paid labor force, while 80 percent of men do. Across countries, the gender wage gap persists at around 20 percent, on average. Women work in lower-paying occupations and jobs. Across the globe, only 1 in 5 firms have a female top manager. While these outcomes might in part reflect optimizing decisions within the family (for example, see Chioda, 2016, for evidence from Latin America), evidence shows that a variety of constraints explain some portion of these gaps, ranging from the lack of child care and adequate leave policies to social norms that create barriers to women working. These norms include those that put a disproportionate responsibility for domestic work and child care on women, as well as those that result in occupational sex segregation, sexual harassment, and mobility restrictions. Women must also contend with differential constraints in access to finance and markets, a great divide in access to digital technology, and legal/regulatory barriers to start and grow firms. All these factors result in wasted potential in terms of realizing economics gains from human capital investments in girls. Looking only at the sex-disaggregated HCI misses an important reality concerning gender gaps in how human capital is utilized.

For human capital to translate into productivity, the human, who owns the capital, needs to be employed in work where they can use their human capital. In 2020, boys and girls growing up in Peru have the same HCI score of 0.6. However, only 62 percent of women in Peru are employed, compared to 78 percent of men, resulting in a basic UHCI that is 10 percentage points lower for females than for males.

Countries can act to enable women’s full participation in labor market opportunities. Provision of affordable child care options, parental leave policies, and flexible work options can accommodate women’s entry into formal work and help women and men redistribute and balance demands at home and at work. Safe transport allows women to go to the workplace, while pay transparency can increase women’s power to negotiate equal pay for equal work. Improved access to digital technology for women can unlock potential gains from the digital era. These range from accessing online education to expanded income-generating opportunities through flexible online gig work and e-commerce entrepreneurship. Resources need to be mobilized to ensure that women and men have equal access to livelihoods and economic opportunities.

Informing policies to protect and build HUMAN CAPITAL
The HCI 2020 update appears in a context of urgent choices for policy makers in all countries. Strategic decisions made now have the power to protect and strengthen countries’ human capital, and with it their economic future.

In addition to documenting pre-COVID-19 changes in human capital across 174 countries, the HCI 2020 update has established a baseline for tracking the pandemic’s future effects on human capital. A further task for the update has been identifying pathways of influence from COVID-19 to human capital outcomes in the short and longer terms. This may facilitate the identification of entry points for policy. Using the HCI methodology to quantify the gaps that will likely emerge in health, skills, and knowledge because of COVID-19, this analysis underscores the urgency of protecting and sustaining the recovery of human capital, which will be a cornerstone of countries’ postcrisis recovery and future economic growth.

Good measurement and data are essential for these policies to be well targeted and cost-effective. But effective policies do not arise from thin air. They are shaped and guided, and repeatedly undergo course corrections using the evidence that reliable measurement can provide.

To underscore this point, this report’s final pages identify key ways measurement and data can contribute to policy success; map short-term and longer-range agendas for strengthening the measurement of human capital; and link them to several specific policy changes necessary to protect human capital in the wake of COVID-19.

5.1 GOOD MEASUREMENT: NECESSITY, NOT LUXURY

As the COVID-19 crisis continues to unfold, good data and measurement are more vital than ever. Yet fiscal constraints and numerous competing priorities raise the risk that the need for urgent action delays the investments required in measurement. In fact, measurement enables effective action.

Better measurement and transparent information can be transformational in safeguarding and strengthening human capital. By generating a shared understanding among diverse actors, measurement can shine a light on constraints that limit progress in human capital. Through this process, effective measurement can facilitate political consensus based on facts and muster support for reforms. Measurement also enables policy makers to target support to those who are most in need, which is often where interventions yield the highest payoffs. As policy implementation moves forward, measurement provides feedback to guide course corrections.

If measurement can improve policy results around human capital in ordinary times, its importance is multiplied during a crisis. Governments that can access and use relevant data in real time are better able to act in a coordinated way on multiple fronts. In the case of COVID-19, they can monitor the evolution of disease transmission and continuously update control strategies, while responding to the immediate and long-term effects of the economic crisis on households and communities. Measuring how well children are growing, whether they are learning, and how financial stress and insecurity are...
affecting their development is a necessity, not a luxury. It is essential to design and target policies that can remediate the pandemic’s negative impacts. At a time when demand for government spending is surging, and fiscal space is limited, data and its transparent communication are vital to ensure accountability for how scarce resources are used.

The power of measurement to support transformative action in difficult situations extends beyond public health emergencies. For example, data are especially important in countries affected by fragility or conflict, though measurement is far more difficult to carry out in these settings. Insecurity and the lack of robust institutions hinder data collection and, in turn, the ability of governments to take action informed by evidence. Fortunately, innovative methods have recently enabled some progress in understanding human capital dynamics in fragile contexts (Box 5.1).

5.2 BEYOND THE HUMAN CAPITAL INDEX

The HCI offers a bird’s-eye view of human capital across countries. By benchmarking the productivity costs of shortfalls in health and education, the index has catalyzed new conversations within governments, bringing discussion on human capital accumulation to the level where decisions about resource allocation are actually made. This is an important achievement.

However, as a measurement tool, the HCI has substantial limitations. For example, it does not speak to distributional or geographical differences within countries. And while it focuses on what matters—outcomes—it does not chart the specific pathways that each country needs to follow to accelerate progress in human capital. Much greater depth in measurement and research is needed to better understand the dynamics of human capital accumulation, including across socio-economic groups and geography, and how policies can affect it. Some key measurement improvements can be achieved in the short term (for example on test scores, see Box 5.2). Longer-term efforts will demand a more sustained commitment from countries and development partners.

5.2.1 A short-term measurement agenda

Due to the dramatic changes in household incomes and service delivery driven by COVID-19, there is an immediate need to measure the pandemic’s welfare impacts. However, social distancing is limiting the way in which traditional surveys are collected by enumerators who visit families. Phone surveys have helped answer this challenge by helping reach households remotely and cheaply. Various research centers and institutions, including the World Bank, have implemented phone surveys in the wake of COVID-19. Emerging evidence from these surveys confirms that family incomes have dropped rapidly in many settings, and that a large share of families have become food insecure.

Phone surveys are relatively inexpensive, which is important at a moment when resources are especially scarce and countries face many competing priorities. They are well suited for gathering information about behaviors (including access to health services and uptake of remote learning arrangements) or outcomes (such as income and consumption) subject to rapid variation. They are likely to return more reliable and informative data when they build on existing information bases, pointing to the importance of triangulating with existing initiatives.

Facility phone surveys are a complement to household phone surveys. These can document, for example, how prepared health facilities are to manage COVID-19 patients and identify bottlenecks

1 Some of the emerging messages from these surveys are summarized in chapter 3 of this report.
Box 5.1: Innovative data collection in fragile contexts: Examples from West Africa and the Middle East and North Africa

Epidemics affect people’s health, and they also disrupt livelihoods and well-being through school closures, workers placed on furlough, restrictions on transportation and gatherings, and closing of international borders. As such, at the height of the Ebola epidemic in West Africa, in addition to assessing the impact of the disease on people’s health, it was also important to measure and monitor the epidemic’s socio-economic impact. However, given the nature of the epidemic, it was impossible and unethical to deploy enumerators to the field for data collection in face-to-face interviews at households and in communities. In 2014, capitalizing on the proliferation of mobile phone networks, and building on the experiences of the mobile phone survey initiative called Listening to Africa (L2A), high-frequency mobile phone interventions were designed and implemented to provide rapid monitoring of the socio-economic impacts of the Ebola crisis in Liberia and Sierra Leone.

Two nationally representative surveys, each conducted in Liberia and Sierra Leone when the crisis broke out, were used as the baseline for anchoring estimates in a representative dataset. In Liberia, researchers drew on the country’s Household Income and Expenditure Survey, which had to curtail fieldwork in August 2014. In Sierra Leone, they used the Labor Force Survey, which had completed fieldwork in July 2014. These existing surveys provided a database of phone numbers and household characteristics, which eventually became the sample frame for the phone survey. Data were then collected through call centers either nationally or internationally to reach over two thousand respondents in each country. Although phone surveys cannot replace face-to-face household surveys in all contexts, the experience in Liberia and Sierra Leone illustrated substantial benefits of such innovation in specific circumstances and for specific data collection needs, particularly the ability to collect timely data in volatile and high-risk environments.

Implementing surveys in a rapidly evolving context involves myriad challenges, including the lack of a relevant and reliable sample frame. For example, excluding displaced populations from national sample frames threatens the representativeness of socioeconomic surveys and consequently provides a skewed understanding of the country. As the size of forcibly displaced populations increases globally, it is urgent to devise strategies to include these populations in nationally representative surveys. The sampling procedure undertaken for the Syrian Refugee and Host Community Surveys (SRHCS), implemented in Lebanon, Jordan, and the Kurdistan region of Iraq over 2015-2016, offers valuable insights on overcoming survey-implementation challenges to obtain representative estimates in challenging contexts. In the absence of updated national sample frames for host communities, and given the lack of comprehensive mapping of forcibly displaced populations, geospatial segmenting was used to create enumeration areas where they did not exist. Data collected by humanitarian agencies, including the United Nations High Commissioner for Refugees (UNHCR) and the International Organization for Migration (IOM), were used to generate sample frames for displaced populations.

Source: Based on Hoogeveen and Pape (2020).
Box 5.2: Leveraging National Assessments to Obtain Internationally Comparable Estimates of Education Quality

The HCI highlights the need for regular and globally comparable measurement of learning to assess the quality of a country’s education system. Although most data on education quality included in the HCI currently come from assessments that are designed to be comparable across countries and over time using psychometric methods, they are often infrequent and do not yet cover all countries.

Leveraging national learning assessments can help bridge the gaps in learning data. Most countries regularly conduct some form of assessment that can be augmented with short modules of globally benchmarked and validated items to construct globally comparable measures of education quality.\(^a\) Though there is no comprehensive bank of globally benchmarked items, there are items from international assessments that can be incorporated into national assessments as “linking items”. These linking items provide commonality with international assessments, enabling learning outcomes to be placed on a global scale.\(^b\) For instance, the 2021 National Assessment for Secondary Schools will enable Bangladesh to produce globally comparable learning outcomes. To allow comparison of national education quality on a global scale, the following countries have recently fielded or are planning to include linking items from international assessments in their national assessments.

**Sri Lanka.** In 2009, the national assessment included linked TIMSS items. Subsequent national assessments in the country have maintained linking items with TIMSS to allow international comparability. The score produced from the national assessment is used in the World Bank’s HCI.

**Uzbekistan.** Before 2019, there was no internationally comparable learning outcomes data available for Uzbekistan. The launch of the 2018 HCI galvanized the government toward measurement of education quality, and in 2019, with the support of the World Bank, the country conducted its first ever nationally representative and internationally comparable assessment (using TIMSS linking items) for grade 5 students in Mathematics, now part of the country’s 2020 HCI.

**Nigeria.** Besides an Early Grade Reading Assessment conducted in 2014 for only four of the 37 states in the country, Nigeria’s learning data had been sparse until recently. The HCI 2018 emphasized the need for a nationally representative and internationally comparable assessment of learning outcomes in Nigeria. The Nigerian National Learning Assessment (NLA 2019), supported by the World Bank, is the first nationally representative learning assessment conducted in Nigeria using an internationally recognized methodology. The NLA 2019 measures student learning at grade 4 and grade 8 in core subjects of Mathematics, English, and Science and includes linking items to allow comparison on an international scale. Although not yet available, it will allow for inclusion in a future HCI of a nationally representative and globally comparable learning measure for Nigeria.

Relatively few linking items are currently available from international assessments, necessitating a cautious approach informed by country contexts: ensuring that the selected linking items align with the country’s national grade-level curriculum, are translated according to the protocols of the international assessment, are piloted in the country, and are not too easy or too difficult for the target population; that similar testing conditions are arranged as for international assessments; and that a sufficient number of items are selected to provide reliable internationally comparable estimates of education quality in the country.

\(^a\) Birdsall, Bruns, and Madan (2016) and UNESCO (2018).
\(^b\) Kolen and Brennan (2004).
in the delivery of routine health services, including immunization and maternal and child health services. Administrative data can also be used to monitor many aspects of service provision—at a low marginal cost, because these data already exist in most countries. These existing datasets could provide valuable insights, but they are often poorly linked, of varying quality, and inaccessible to groups outside of government. Similarly, big data can also be leveraged. For example, data from mobile phone records have been used to monitor mobility (which is important to modulate disease containment), to nudge behavior, and to improve service delivery, including delivering educational content. Digital technology and data can be harnessed to provide social protection benefits more equitably and efficiently, both in the immediate and in the longer run.

### 5.2.2 Tackling long-term measurement needs

In addition to solutions that can be deployed rapidly, countries need strategies to improve the measurement of human capital in the longer run.

The process of creating the 2020 HCI update has brought that message home. The process of data curation for this update has been a productive opportunity to improve data quality jointly with counterparts. For example, thanks to close collaboration with the Ministry of Human Resource Development in India, it was possible to significantly improve upon publicly available data for school enrollment and arrive at a measure of expected years of school (EYS) constructed on the basis of actual age-specific enrollment rates, which capture enrollment more precisely.2

However, many gaps in the measurement of internationally comparable key dimensions of human capital still persist (Box 5.2). For example, establishing well-functioning vital registry systems to record such basic events as births and deaths is still a work in progress: less than 70 percent of countries record such events, and progress to fill these gaps has been slow (Box 5.3). The quality of school enrollment data, which in the index is based on administrative records, is highly variable in low- and middle-income countries, particularly for the lower and upper secondary cycle. Finally, benchmarking learning outcomes internationally has been a challenge, both across countries and especially over time. This has significantly constrained the coverage of the long-run analysis of changes in measured human capital. These challenges are heightened in fragile countries: in some cases, data to inform various HCI components simply do not exist; in others, data are too old and likely do not sufficiently capture the rapid deterioration of human capital that can occur in fragile contexts. In addition, comparable data, including over time, for refugees, displaced persons, and host populations are extremely limited.

An upcoming World Development Report will be focused on data, and this report is not the place for a comprehensive description of the complex and rapidly evolving measurement landscape. However, it is worth touching on several areas where better-funded and coordinated data collection and use could improve the understanding of human capital accumulation and effective interventions to accelerate it.

One such area concerns the long-term consequences of interventions that have proved successful in the short run. For example, there is well-established evidence that conditional cash transfers (CCTs) have improved a variety of health and education outcomes within a few years of program inception. However, there is relatively little

---

2 Expected years of school, conceptually, is just the sum of enrollment rates by age from age 4 to age 17. However, since age-specific enrollment rates are seldomly available, data on enrollment rates by level of school are used to approximate enrollment rates for the age bracket. In India, enrollment rates provided and used for EYS calculation are age specific and thus there is no need to approximate the values.
evidence on whether and how the increased time spent in school under the CCT led to better learning outcomes and improved labor market opportunities. Projects should be prepared to monitor a wide variety of potential outcomes, including educational attainment, socioeconomic changes, and health indicators. Similarly, long-term evidence on the efficacy of some types of interventions often relies on findings from small pilots that were not followed by country wide scale-up, and questions therefore remain about the generalizability of promising findings.

Administrative data—for example, linking educational assessments and hospital records to taxation records, social security contributions, or health insurance via unique identifiers—allow such evaluations. The benefits of user-friendly administrative data systems are vast, since they can inform policy choices about the design of cost-effective interventions, allow regular monitoring of key outcomes, and support decision-making in real time, all at low marginal cost. However, within a country, administrative data are collected by a variety of ministries and other entities, often resulting in a patchwork of systems that does not favor integration and optimal use. Taking advantage of these data requires expertise that is scarce in many countries. Finally, legitimate privacy concerns also restrict access and can make data linking incomplete or impossible.

A related question is understanding the “production function” of health and education outcomes from the service delivery perspective. This issue is essential for designing effective interventions and systems for quality health care and education. It is even more pressing now in a post-COVID-19 world, where extensive remediation will be needed to compensate for the losses of human capital caused by the shock. Unanswered questions are numerous and start at a basic level. Do students have textbooks? Are health centers stocked with the necessary drugs?

Beyond assessing fundamental inputs, countries need answers on how to improve quality. These include understanding whether teachers actually master the curriculum they are teaching and if physicians diagnose diseases and treat them appropriately. Selection mechanisms and incentives also matter for the quality of services. For example, pay for performance has been widely introduced and requires evaluation. How can it best be managed and at what level? Private-sector financing and delivery also have the potential to improve service quality. But how can countries make sure that quality improves while services remain affordable? Rapid advances in information and communications technology (ICT) likewise hold promise to improve service delivery. But reliable strategies to make this happen are not obvious and will differ across country contexts. Additionally, quality reflects management capacities and choices. What management interventions improve service delivery in cost-effective ways? And how can countries measure the quality of management itself in the social sectors?

Administrative data can answer some of these questions but cannot provide insights into behaviors and competencies. Surveys such as the Service Delivery Indicators (SDI) can help. SDI are nationally representative facility surveys that measure the quality of services received by average citizens in primary health care centers and primary schools. SDI collects data on critical inputs and provider performance, and in the case of schools, children’s learning. These types of data allow governments and service providers to identify gaps in service provision, link financing inputs with health and education outcomes, and understand the margins along which social sector spending fails to translate into quality services. SDIs are important
platforms for innovation and research, including measuring the quality of management in schools and hospitals.

The analysis of delivery systems needs to advance in parallel with a deeper understanding of how human capital accumulates through the life course. For example, evidence points to the nodal importance of early childhood years for lifelong cognitive, physical, and socioemotional development. However, systematic measurement of skills in early years is a prerogative of very few countries. Even when those measures are available, the evolution of health status, cognitive abilities, and non-cognitive skills during early childhood is not well understood. Similarly, measuring skill—cognitive and non-cognitive—among adolescents and adults is still rare in most countries.

Advancing the long-term measurement agenda just described will require purposeful investments. In turn, funding measurement is a way to increase the efficiency and impact of future policy action across multiple domains. By supporting the political economy of reform processes and guiding policy choices towards cost-effective solutions, better measurement and data use are investments that pay off.

5.3 BUILDING, PROTECTING, AND EMPLOYING HUMAN CAPITAL IN A POST PANDEMIC WORLD

Governments are now working under intense pressure to roll out policies across multiple sectors in response to COVID-19. Measurement is essential to ensure that these policies are strategically designed and well implemented, and that they get results. What might effective policy solutions look like, in the domains most important for human capital? While a companion paper to the HCI 2020 update (World Bank, 2020b) discusses policy responses to COVID-19 in detail, below are some of the broad directions these responses may adopt.

5.4 A DATA-DRIVEN HEALTH SECTOR RESPONSE

The immediate priority for countries fighting COVID-19 remains containment and elimination of the novel coronavirus. Global efforts, such as improvements in testing and access to a safe and effective vaccine, will need to accompany local measures to test, trace, and isolate carriers of infection; to support the use of non-pharmaceutical interventions such as masks and social distancing; and to implement targeted lockdowns when necessary. Strengthening public health surveillance capacity will be essential to the timeliness and effectiveness of these interventions. Robust surveillance requires the ability to collect, analyze, and interpret relevant health-related data and use these data to plan, implement, and evaluate control actions. With most pandemics being of zoonotic origin, closer coordination between health and the agriculture sector will be instrumental to prevent future outbreaks, in keeping with a “one health” approach.

Complementing strong surveillance, it is essential to step up health services to care for COVID-19 patients while maintaining the delivery of core health services. COVID-19 highlights the need to invest in primary health care, with strong frontline delivery systems. In low- and middle-income countries, priority measures to strengthen primary health care may focus on reproductive and child health and nutrition; infectious disease control programs for HIV, tuberculosis, and malaria; and community-based health promotion and disease prevention. In middle- and higher-income countries, a focus on improving healthy longevity, addressing non-communicable diseases, and linking primary care practitioners more tightly to disease surveillance networks will go a long way toward increasing resilience. In the face of widening health disparities, it is essential to ensure that disadvantaged households and communities have access to quality and affordable care. In the past, disruptions of the health and economic
Box 5.3: Data quality and freshness in the components of the Human Capital Index

The HCI has proved a useful tool for policy dialogue, in large part because it incorporates human capital outcomes that are easily recognizable, consistently measured across the world, and salient to policy makers. While there are multiple aspects of human capital that can be measured in sophisticated ways, the relatively straightforward components of the HCI provide a snapshot of some of the most vital aspects of human capital accumulation. And while this section makes a case for better measurement of aspects of human capital outside the HCI, it is worth noting that even the fundamental components included in the index suffer from significant data gaps and quality issues.

The components of child and adult survival used to compute the HCI are based on data on birth and death rates by age group. These data are primarily sourced from national vital registries that are mandated to record the occurrences and characteristics of vital events like births and deaths. Vital statistics are essential to the measurement of demographic indicators like life expectancy and to identifying health priorities for the population. Vital statistics can also help target health interventions and monitor their progress. However, the coverage of vital registries varies widely; only 68 percent of countries register at least 90 percent of births that have occurred and only 55 percent of countries cover at least 90 percent of deaths (see panels A and B). Birth registration has increased by only 7 percentage points (from 58 percent to 65 percent) in the past decade, and in Sub-Saharan Africa, only eight countries have coverage of 80 percent or more for under-5 birth registration.

Stunting serves as an indicator for the prenatal, infant, and early childhood health environments. The JME database that collates and reports global stunting data reports data for 152 countries, of which 33 have data that are more than five years old. In 10 countries, the most recent survey is over 10 years old.

Gaps also remain in education data. The EYS measure is based on enrollment data that national governments provide to the UNESCO Institute for Statistics (UIS). Of the 174 countries that form part of the HCI 2020 sample, 22 countries rely on primary enrollment data that come from 2015 or earlier. Since primary enrollment data are typically the most consistently reported, the issue of data freshness is of even greater concern for other levels of school. There are also significant gaps in time series data on enrollment rates. Of the 103 countries included in the 2010 HCI sample, 22 countries were missing primary enrollment rates for 2010. Data gaps are more numerous at other levels of schooling—over 30 countries were missing secondary-level enrollment data for 2010, and 42 countries were missing these data at the pre-primary level.

Finally, the latest update to the Global Dataset on Education Quality that produces the harmonized test scores covers 98.7 percent of the school-age population. However, of the 174 countries that have an HCI, 14 rely for test score data on Early Grade Reading Assessments (EGRAs) that are not representative at the national level. A total of 65 countries (roughly 37 percent of the sample) rely on test score data that are from 2015 or earlier.

There are also significant gaps in sex-disaggregated data across HCI components. The JME reports disaggregated stunting data for only 56 percent of the 887 surveys that are part of
the database. While sex-disaggregated enrollment rates are reasonably complete at the primary level, they are missing at the lower secondary level for 29 of the 174 countries that are part of the HCI 2020 sample. Sixteen countries in this sample are also missing disaggregated test score data. As a result of these gaps, 21 of the 174 countries in the 2020 sample do not have sex-disaggregated HCI scores. These gaps in disaggregated data span all regions and income groups.

The credible and consistent measurement of human capital outcomes is essential to identifying priority areas for policy intervention, informing the design of those policies and tracking their effectiveness over time. While high-quality data collection can doubtless be a costly undertaking, countries can also explore more cost-effective ways of monitoring the health and education outcomes of their citizens. For instance, instead of bearing the costs of participating in an international assessment like PISA or TIMSS, Uzbekistan incorporated assessment items into their national learning assessment that would allow for a linking with TIMSS (see Box 5.2).

**Panel A: Coverage of live births registration**
status quo have sometimes enabled countries to introduce bold health-system reforms. In that sense, these difficult times may offer an unexpected opportunity in many countries to renew the commitment to universal health coverage.

---

5 World Bank (2020c).
5.5 PREVENTING LOSSES IN LEARNING

Along with more and better investments in health, a broad range of interventions are needed in other sectors to get human capital accumulation back on track, both in the short and longer terms. Due to school closures and economic hardships, the current generation of students stands to lose significantly in terms of learning and non-cognitive skills now, and to lose earnings later in life. Strategies to remediate schooling losses will require designing and implementing school re-opening protocols adapted to the specificities of the pandemic. At a minimum, these will involve protective equipment and supplies, health screening, and social distancing. Tailored teaching and learning resources, especially for disadvantaged children, are urgently needed in many settings to make up for lost learning.

Deeper reforms will need to follow to sustain access to schooling and promote children’s learning at all stages: starting from cognitive stimulation in the early years, to nurturing relevant skills in childhood and adolescence. Building blocks for success will include better-prepared teachers, better-managed schools, and incentives that are aligned across the many stakeholders in education reform. The efforts that countries have made in providing continuity with remote learning during the pandemic could carry benefits beyond the current emergency. Appropriately structured online learning can facilitate the acquisition of those competencies, such as collaboration and higher-order cognitive skills, that are increasingly essential in the changing world of work. To shape resilient education systems, countries will need to draw lessons from this worldwide distance-learning experience and expand the infrastructure for online and remote learning.

5.6 REINFORCING RESILIENCE AMONG VULNERABLE PEOPLE AND COMMUNITIES

In the face of sharp declines in income, support to poor and vulnerable households is essential to mitigate the crisis impact and to sustain access to services and food security. In the first phase of the pandemic response, the consensus on social assistance programs has been to cast the net wide, to avoid excluding any of those in need. In the medium-term, these interventions need to be reassessed and complemented or replaced by policy measures geared toward an inclusive and sustainable economic recovery with support for employment and livelihoods (including with active labor market policies that help match workers to new jobs and upgrade their skills), as well as assistance to small and micro-enterprises. In parallel, strengthening social services, including counseling, will help mitigate impacts on mental health and disruptions in people’s social networks.

COVID-19 has exacerbated many forms of inequality, notably gender gaps. School closures and a reduction in health services can interrupt the trajectories of adolescent girls at a critical life juncture. With women-owned firms primarily concentrated in informal or low-paying sectors, the lack of basic formal social protection excludes women and their families from buffers against economic shocks, exactly at a time when they are being hit the hardest. Risks of gender-based violence can also be heightened during times of crisis, isolation, and confinement. These effects are amplified in fragile settings.

Deepening inequalities make targeting interventions to the most disadvantaged—and particularly to children in their early years—an imperative.
to prevent setbacks that are likely to compromise lifetime health, education, and socioeconomic trajectories among the most vulnerable. These interventions should have an explicit gender angle to help progressively close the gaps that are now being magnified by COVID-19.

5.7 COORDINATING ACTION ACROSS SECTORS AND ADOPTING A WHOLE-OF-SOCIETY APPROACH

COVID-19 has underscored the interdependence that exists among multiple sectors that are fundamental for human capital accumulation. These include health, education, infrastructure, water and sanitation, information technology, and others. Complex linkages connect these domains. For example, proper hygiene contributes to limiting diffusion of the virus. In turn, reduced transmission is often a pre-condition to re-open schools. Digital technologies enable educational continuity when physical re-opening cannot be achieved. But many poor and marginalized communities lack access to digital tools. These links point to the need for ambitious infrastructure and other investments in many countries to expand access to water, sanitation, and digitalization as key enablers of human capital accumulation.

Connections across sectoral and social boundaries emphasize the value of policy approaches that engage diverse stakeholders. Nurturing a nation’s human capital is everybody’s business. If a child accumulates strong human capital during her critical years of growth and development, it is because a large network of people and institutions have contributed to the process. Parents decide what to feed a child, when to take her to the doctor, and whether and for how long to send her to school. Families make these choices within communities that transmit norms and may help households in need. In turn, communities rely on services that, in many contexts, are provided largely by the private sector, including non-governmental organizations. Finally, governments act to provide public goods, address externalities, and ensure equity. Wise public policy choices, informed by measurement, facilitate the shared achievement of human capital, and make it more than the sum of its parts.

The COVID-19 crisis has put all the links in this network under strain, not least the governments themselves. Under these conditions, progress depends on leadership that recognizes the importance of building a future in which all children can reach their potential. In the months and years ahead, with limited fiscal space, protecting core spending for human capital will challenge policymakers in many countries, regardless of their levels of income. Yet, by making these investments with a view to the future, countries can emerge from the COVID-19 crisis prepared to do more than restore the human capital that has been lost. Ambitious policies informed by rigorous measurement can take human capital beyond the levels previously achieved, opening the way to a more prosperous and inclusive future.

APPENDICES
Appendix A:
The Human Capital Index: Methodology
1. COMPONENTS OF THE HCI

The Human Capital Index (HCI) measures the human capital that a child born today can expect to attain by age 18, given the risks to poor health and poor education that prevail in the country where she lives. The HCI follows the trajectory from birth to adulthood of a child born today. In the poorest countries in the world, there is a significant risk that the child will not survive to her fifth birthday. Even if she does reach school age, there is a further risk that she will not start school, let alone complete the full cycle of 14 years of school from preschool to grade 12 that is the norm in rich countries. The time she does spend in school may translate unevenly into learning, depending on the quality of the teachers and schools she experiences. When she reaches age 18, she carries with her the lasting effects of poor health and nutrition from her childhood that limit her physical and cognitive abilities as an adult.

The HCI quantitatively illustrates the key stages in this trajectory and their consequences for the productivity of the next generation of workers, with three components:

Component 1: Survival. This component of the index reflects the unfortunate reality that not all children born today will survive until the age when the process of human capital accumulation through formal education begins. It is measured using the under-5 mortality rate (Figure A.1), with survival to age 5 as the complement of the under-5 mortality rate.

Component 2: School. This component of the index combines information on the quantity and quality of education;

- The quantity of education is measured as the number of years of school a child can expect to obtain by age 18 given the prevailing pattern of enrollment rates (figure A.1). The maximum possible value is 14 years, corresponding to the maximum number of years of school obtained as of her 18th birthday by a child who starts preschool at age 4. In the data, expected years of school range from around 4 to close to 14 years.
- The quality of education reflects work at the World Bank to harmonize test scores from major international student achievement testing programs into a measure

---

1 This appendix provides a summary of the methodology for the Human Capital Index. For additional details, see Kraay (2018), on which this appendix is based.
of harmonized test scores (HTSs). HTSs are measured in units of the Trends in International Mathematics and Science Study (TIMSS) testing program and range from around 300 to around 600 across countries (figure A.1).

Tests scores are used to convert expected years of school into quality-adjusted years of school. Quality-adjusted years of school are obtained by multiplying expected years of school by the ratio of test scores to 625, corresponding to the TIMSS benchmark of advanced achievement. For example, if expected years of school in a country is 10 and the average test score is 400, then the country has $10 \times \left(\frac{400}{625}\right) = 6.4$ quality-adjusted years of school. The distance between 10 and 6.4 represents a learning gap equivalent to 3.6 years of school.

**Component 3: Health.** There is no single broadly accepted, directly measured, and widely available summary measure of health that can be used in the same way as years of school as a standard measure of educational attainment. Instead, two proxies for the overall health environment are used:

*Adult survival rates.* This is measured as the share of 15-year-olds who survive until age 60. This measure of mortality serves as a proxy for the range of nonfatal health outcomes that a child born today would experience as an adult if current conditions prevail into the future.

*Healthy growth among children under age 5.* This is measured as the fraction of children who are not stunted, that is, as 1 minus the share of children under 5 whose height-for-age is more than two standard deviations below the World Health Organization Child Growth Standards’ median. Stunting serves as an indicator for the prenatal, infant, and early childhood health environment, summarizing the risks to good health that children born today are likely to experience in their early years, with important consequences for health and well-being in adulthood.

Data on these two health indicators are shown in figure A.1. Data for all the components of the HCI 2020 by country are reported in Table C2.3.

**Aggregation methodology**
The components of the HCI are combined into a single index by first converting them into contributions to productivity. Multiplying the contributions to productivity gives the overall HCI. The HCI summarizes how productive children born today will be as members of the future workforce, given the risks to education and health summarized in the components. The HCI is measured in units of productivity relative to a benchmark corresponding to complete education and full health.

---

2 The methodology for harmonizing test scores is detailed in Altinok, Angrist, and Patrinos (2018) and Patrinos and Angrist (2018).
3 This methodology was introduced by the World Bank (2018) and is elaborated on in Angrist et al. (2019).
4 This approach has been used extensively in the development accounting literature (for example, Caselli, 2005; Hsieh and Klenow, 2010). The approach for health closely follows Weil (2007). Galasso and Wagstaff (2016) apply a similar framework to measure the costs of stunting.
In the case of survival, the relative productivity interpretation is stark: children who do not survive childhood never become productive adults. As a result, expected productivity as a future worker of a child born today is reduced by a factor equal to the survival rate, relative to the benchmark where all children survive.

In the case of education, the relative productivity interpretation is anchored in the large empirical literature measuring the returns to education at the individual level. A rough consensus from this literature is that an additional year of school raises earnings by about 8 percent. This evidence can be used to convert differences in quality-adjusted years of school across countries into differences in worker productivity. For example, compared with a benchmark where all children obtain a full 14 years of school by age 18, a child who obtains only 10 years of education can expect to be 32 percent less productive as an adult (a gap of four years of education, multiplied by 8 percent per year).

In the case of health, the relative productivity interpretation is based on the empirical literature measuring the economic returns to better health at the individual level. The key challenge in this literature is that there is no unique directly measured summary indicator of the various aspects of health that matter for productivity. This literature often uses proxy indicators for health, such as adult height, in the same way that the HCI uses proxy indicators. This is because adult height can be measured directly and reflects the accumulation of shocks to health through childhood and adolescence. A rough consensus drawn from this literature is that an improvement in health associated with a 1 centimeter increase in adult height raises productivity by 3.4 percent.

Converting this evidence on the returns to one proxy for health (adult height) into the other proxies for health used in the HCI (stunting and adult survival) requires information on the relationships between these different proxies.

For stunting, there is a direct relationship between stunting in childhood and future adult height because growth deficits in childhood persist to a large extent into adulthood, together with the associated health and cognitive deficits. Available evidence suggests that a reduction in stunting rates of 10 percentage points increases attained adult height by approximately one centimeter (0.1 × 10.2), which increases productivity by 3.5 percent.

For adult survival, the empirical evidence suggests that, if overall health improves, both adult height and adult survival rates increase in such a way that adult height rises by 1.9 centimeters for every 10-percentage-point improvement in adult survival. This implies that an improvement in health that leads to an increase in adult survival rates of 10 percentage points is associated with an improvement in worker productivity of 1.9 × 3.4 percent, or 6.5 percent.

---

5 The seminal methodology is due to Mincer (1958). See Montenegro and Patrinos (2014) for recent cross-country estimates of the returns to schooling.
6 For example, see Case and Paxson (2008); Horton and Steckel (2011).
7 For details, see Weil (2007) and Kraay (2018), section A3, and accompanying references.
In the HCI, the estimated contributions of health to worker productivity based on these two alternative proxies are averaged (if both are available) and are used individually (if only one of the two is available). The contribution of health to productivity is expressed relative to the benchmark of full health, defined as the absence of stunting, and a 100 percent adult survival rate. For example, compared with a benchmark of no stunting, in a country where the stunting rate is 30 percent, poor health reduces worker productivity by $30 \times 0.34$ percent, or 10 percent. Similarly, compared with the benchmark of 100 percent adult survival, poor health reduces worker productivity by $30 \times 0.65$ percent, or 19.5 percent, in a country where the adult survival rate is 70 percent. The average of the two estimates of the effect of health on productivity is used in the HCI.

The overall HCI is constructed by multiplying the contributions of survival, school, and health to relative productivity, as follows:

$$HCI = Survival \times School \times Health,$$

with the three components defined as:

$$Survival \equiv \frac{1 - Under 5 Mortality Rate}{1} \quad (2)$$

$$School \equiv e^{\phi(\text{Expected Years of School} \times \text{Harmonized Test Score} - 14)} \quad (3)$$

$$Health \equiv e^{(\gamma_{\text{ASR}}(Adult Survival Rate-1) + \gamma_{\text{Stunting}}(Not Stunted Rate-1))/2} \quad (4)$$

The components of the index are expressed here as contributions to productivity relative to the benchmark of complete high-quality education and full health. The parameter $\phi = 0.08$ measures the returns to an additional year of school. The parameters $\gamma_{\text{ASR}} = 0.65$ and $\gamma_{\text{Stunting}} = 0.35$ measure the improvements in productivity associated with an improvement in health, using adult survival and stunting as proxies for health. The benchmark of complete high-quality education corresponds to 14 years of school and a harmonized test score of 625. The benchmark of full health corresponds to 100 percent child and adult survival and a stunting rate of 0 percent.

These parameters serve as weights in the construction of the HCI. The weights are chosen to be the same across countries, so that cross-country differences in the HCI reflect only cross-country differences in the component variables. This facilitates the interpretation of the index. This is also a pragmatic choice because estimating country-specific returns to education and health for all countries included in the HCI is not feasible.

As shown in figure A.1, child survival rates range from around 90 percent in the highest-mortality countries to near 100 percent in the lowest-mortality countries. This implies a loss of productivity of 10 percent relative to the benchmark of no mortality. Quality-adjusted years of school range from around 3 years to close to 14 years. This gap in quality-adjusted years of school implies a gap in productivity relative to the benchmark of complete education of $e^{\phi(14 - 1)} = e^{0.08(13)} = 0.4$; that is, the productivity of a
future worker in countries with the lowest years of quality-adjusted school is only 40 percent of what it would be under the benchmark of complete education. For health, adult survival rates range from 60 to 95 percent, while the share of children not stunted ranges from around 60 percent to over 95 percent. Using adult survival rates indicates a gap in productivity of \( e^{\gamma_{ASR}(0.6-1)} = e^{0.65(-0.4)} = 0.77 \). Thus, based on adult survival rates as a proxy for health, the productivity of a future worker is only 77 percent of what it would be under the benchmark of full health. Using the share of children not stunted leads to a gap in productivity of \( e^{\gamma_{Sstunting}(0.6-1)} = e^{0.35(-0.4)} = 0.87 \). The productivity of a future worker using the stunting-based proxy for health is therefore only 87 percent of what it would be under the benchmark of full health.

2. THE HUMAN CAPITAL INDEX

The overall HCI is displayed in figure 2.1 the main text. The HCI data are available at www.worldbank.org/humancapital. The HCI is, on average, higher in rich countries than in poor countries and ranges from around 0.3 to around 0.9. The units of the HCI have the same interpretation as the components measured in terms of relative productivity. Consider a country such as Morocco, which has an HCI of around 0.5. If current education and health conditions in Morocco persist, a child born today will be only half as productive as she could have been if she enjoyed complete education and full health.

All of the components of the HCI are measured with some error, and this uncertainty naturally has implications for the precision of the overall HCI. To capture this imprecision, the HCI estimates for each country are accompanied by upper and lower bounds that reflect the uncertainty in the measurement of the components of the HCI (figure A.2). These bounds are constructed by recalculating the HCI using lower- and upper-bound estimates of the components of the HCI. The resulting uncertainty intervals are shown in figure A.2 as vertical ranges around the value of the HCI for each country.

The upper and lower bounds are a tool to highlight to users that the estimated HCI values for all countries are subject to uncertainty, reflecting the corresponding uncertainty in the components. In cases where these intervals overlap for two countries, this indicates that the differences in the HCI estimates for these two countries should not be overinterpreted because they are small relative to the uncertainty around the value of the index itself. This is intended to help move the discussion away from small differences in country ranks on the HCI and toward more useful discussions around the level of the HCI and what this implies for the productivity of future workers.

Another feature of the HCI is that it can be disaggregated for girls and boys in the 153 countries where sex-disaggregated data on all of the components of the index are available. Gender gaps are most pronounced in survival to age 5, adult survival, and stunting, where girls, on average, do better than boys in nearly all countries. The number of expected years of school is higher among girls than boys in about two-thirds of the countries, as are test scores. Overall, HCI scores are higher among girls than boys in the majority of countries.
The HCI uses the returns to education and health to convert the education and health indicators into differences in worker productivity across countries. The higher the returns, the larger the resulting worker productivity differences. The size of the returns also influences the relative contributions of education and health to the overall index. For example, if the returns to education are high while the returns to health are low, then cross-country differences in education will account for a larger portion of cross-country differences in the index. Although varying the assumptions about the returns to education and health will affect the relative positions of countries on the index, in practice these changes are small because the health and education indicators are strongly correlated across countries.\(^8\)

**Connecting the Human Capital Index to future growth and income**

The HCI can be connected to future aggregate income levels and growth following the logic of the development accounting literature. This literature typically adopts a simple Cobb-Douglas form for the aggregate production function, as follows:

\[
y = A k_p^\alpha k_h^{1-\alpha}, \tag{5}\]

where \(y\) is GDP per worker; \(k_p\) and \(k_h\) are the stocks of physical and human capital per worker; \(A\) is total factor productivity; and \(\alpha\) is the output elasticity of physical capital. To analyze how changes in human capital may affect income in the long run, it is useful to rewrite the production function as follows:

\[
y = (k_p/y)^{\frac{\alpha}{1-\alpha}} A^{1-\alpha} k_h \tag{6}\]

In this formulation, GDP per worker is proportional to the human capital stock per worker, holding constant the level of total factor productivity and the ratio of physical capital to output, \(\frac{k_p}{y}\). This formulation can be used to answer the question, “By how much does an increase in human capital raise output per worker, in the long run after taking into account the increase in physical capital that is likely to be induced by the increase in human capital?” Equation (6) shows the answer: output per worker increases equiproportionately to human capital per worker, that is, a doubling of human capital per worker will lead to a doubling of output per worker in the long run.

Linking this framework to the HCI requires a few additional steps. First, assume that the stock of human capital per worker that enters the production function, \(k_h\), is equal to the human capital of the average worker. Second, the human capital of the next generation, as measured in the HCI, and the human capital stock that enters the production function need to be linked. This can be done by considering different scenarios. Imagine first a status quo scenario in which the expected years of quality-adjusted school and health as measured in the HCI today persist into the future. Over time, new entrants to the workforce with status quo health and education will replace current members of

---

\(^8\) For more details, see Kraay (2018).
the workforce until eventually the entire workforce of the future has the expected years of quality-adjusted school and health captured in the current human capital index. Let \( k_{h,NG} = e^{s_{NG}} \) denote the future human capital stock in this baseline scenario, where \( s_{NG} \) represents the number of quality-adjusted years of school of the next generation of workers, and \( \gamma z_{NG} \) is shorthand notation for the contribution of the two health indicators to productivity in the HCI in equation (4). Contrast this with a scenario in which the entire future workforce benefits from complete education and enjoys full health, resulting in a higher human capital stock, \( k_h^* = e^{s^*} \), where \( s^* \) represents the benchmark of 14 years of high-quality school, and \( z^* \) represents the benchmark of complete health.

Assuming that total factor productivity and the physical capital-to-output ratio are the same in the two scenarios, the eventual steady-state GDP per worker in the two scenarios is as follows:

\[
y = k_{h,NG} = e^{\phi (s_{NG} - s^*) + \gamma (z_{NG} - z^*)}
\]

This expression is the same as the human capital index in equations (1)–(4) except for the term corresponding to survival to age 5 (because children who do not survive do not become part of the future workforce). This creates a close link between the human capital index and potential future growth. Disregarding the contribution of the survival probability to the HCI, equation (7) shows that a country with an HCI equal to \( x \) could achieve GDP per worker that would be \( 1/x \) times higher in the future if citizens enjoy complete education and full health (corresponding to \( x = 1 \)). For example, a country such as Morocco with an HCI value of around 0.5 could, in the long run, have future GDP per worker in this scenario of complete education and full health that is \( 1/0.5 = 2 \) times higher than GDP per worker in the status quo scenario. What this means in terms of average annual growth rates depends on how long the long run is. For example, under the assumption that it takes 50 years for these scenarios to materialize, then a doubling of future per capita income relative to the status quo corresponds to roughly 1.4 percentage points of additional growth per year.

The calibrated relationship between the HCI and future income described here is simple because it focuses only on steady-state comparisons. In related work, Collin and Weil (2018) elaborate on this by developing a calibrated growth model that traces out the dynamics of adjustment to the steady state. They use this model to trace out trajectories for per capita GDP and for poverty measures for individual countries and global aggregates under alternative assumptions for the future path of human capital. They also calculate the equivalent increase in investment rates in physical capital that would be required to deliver the same increases in output associated with improvements in human capital.

Notes: The figure reports the most recent cross-section of 174 economies for the five HCI components (child survival, expected years of school, harmonized test scores, fraction of children under 5 not stunted, and adult survival), as used to calculate the 2020 HCI. Each panel plots the country-level averages for each component on the vertical and GDP per capita in PPP on the horizontal axis. The dashed line illustrates the fitted regression line between GDP per capita and the respective component. Scatter points above (below) the fitted regression line illustrate economies that perform higher (lower) in the outcome variable than their level of GDP would predict. Countries above the 95th and below the 5th percentile in distance to the fitted regression line are labeled.
Figure A.2: Human Capital Index with uncertainty intervals

Notes: The figure plots the HCI (represented by a dot) and the uncertainty interval of the HCI for each economy.
Appendix B: 

Back-calculated HCI
The first iteration of the Human Capital Index, the 2018 HCI, made use of the best and most recently available data as of 2018. It was calculated for 157 economies. As is common with indices and indicators, comprehensive revisions of the source data were done. For example, GDP series are revised quite often; even international poverty numbers are revised as improved harmonization of survey data is implemented. The reasons for revisions are often to ensure temporal comparability and to incorporate the most accurate data available.

In the case of the HCI, the index makes use of data from different institutions, and most of these institutions release their data annually. What this means is that the index value for 2018 will change, because the newest release of the data has slightly different numbers. In the case of education, the changes are considerably more pronounced, because not only are the underlying data different, but in many cases data that are closer to 2018 are now available. When these elements are assembled to create the back-calculated HCI for 2018, an index that is slightly different from the one published in 2018 emerges (figure B.1). On the y-axis, the countries for which it is now possible to obtain an index in 2018 are shown. These are countries where harmonized test scores are now available for the calculation of the index. Consequently, the number of economies with a back-calculated 2018 HCI is 167, 10 more than for the 2018 HCI. The countries are quite close to the 45-degrees line, with some outliers like Tuvalu, where the 2018 HCI makes use of stunting as a proxy for health, and the back-calculated 2018 HCI makes use of adult mortality. The back-calculated global average for the 2018 index is 0.565 as opposed to 0.567 for the 2018 HCI.

Of course, when looking at individual components, the differences between the 2018 HCI and the back-calculated 2018 HCI are starker. This is particularly relevant for the expected years of school (EYS). With a newer vintage of UNESCO Institute for Statistics (UIS) data, many of the enrollment rates used in the previous round of the HCI have been updated, leading to small changes, so data are added for years that are closer to 2018. This is further complicated because for some economies a preferred rate is now available (TNER>ANER>NER>GER). For example, in most economies where EYS

---

9 See Atamanov et al. (2019) for an example.

10 Stunting rates used in the 2018 HCI corresponded to a 2007 survey. The back-calculated 2018 HCI uses more recent adult mortality rates from 2012, from the World Health Organization, that were not previously available.

11 For details see the description of the construction of the EYS variable in appendix C.
increased by at least half a year, the data come from a year that is closer to 2018, and in many cases there is a move to a preferred enrollment type.

The back-calculated HCI makes use of the better and more recent data available. This allows for an index that better reflects the human capital that a child born in that year could aspire to achieve. The back-calculated HCI 2018 scores by country are reported in Table C2.3.

Notes: Countries not present in the 2018 HCI, but present in the back-calculated HCI on the vertical axis, are Antigua and Barbuda, Dominica, Micronesia, Fed. Sts., Grenada, St. Kitts and Nevis, St. Lucia, Republic of the Marshall Islands, Palau, St. Vincent and the Grenadines, and Samoa.
Appendix C:  

HCI Component Data Notes
1. UNDER-5 MORTALITY RATES

The probability of survival to age 5 is calculated as the complement of the under-5 mortality rate. The under-5 mortality rate is the probability of a child born in a specified year dying before reaching the age of 5 if subject to current age-specific mortality rates. It is frequently expressed as a rate per 1,000 live births, in which case it must be divided by 1,000 to obtain the probability of dying before age 5.

Under-5 mortality rates are calculated by the United Nations Interagency Group for Child Mortality Estimation (IGME) based on mortality as recorded in household surveys and vital registries. The IGME compiles and assesses the quality of all available nationally representative data relevant to the estimation of child mortality, including data from vital registration systems, population censuses, household surveys, and sample registration systems. Globally, birth registration coverage remains inadequate, having increased by only 7 percentage points (from 58 percent to 65 percent) in the past decade. In Sub-Saharan Africa, only eight countries have coverage of 80 percent or more for under-5 birth registration.

The IGME assesses data quality, recalculates data inputs and makes adjustments if needed by applying standard methods. It then fits a statistical model to these data to generate a smooth trend curve that averages over possibly disparate estimates from the different data sources for a country and, finally, it extrapolates the model to a target year. Data are reported annually and cover 198 countries. The IGME estimates are disaggregated by gender and include uncertainty intervals corresponding to 95 percent confidence intervals.

2020 Update

Under-5 mortality rates for the 2020 HCI come from 2019, while data for the back-calculated 2018 HCI come from 2017. Data for the baseline comparator year of 2010

---

come from 2010. Since under-5 mortality rates are estimated by modeling all available child mortality data from vital registration systems, population censuses, household surveys, and sample registration systems, every new release of data from the IGME updates estimates for all the years in the time series. As a result, data for the same past year might differ slightly across updates.

Values for under-5 mortality rates used to produce the back-calculated HCI 2018 are aligned with but not the same as those used in the previous iteration of the HCI, as illustrated in figure C1.1. Data from the two vintages align along the 45-degree line. The figure highlights the four countries where under-5 mortality rates have changed by more than 10 deaths per 1,000 live births or more. The largest revisions were for Nigeria (which went from 100 to 122 deaths per 1,000 live births) and Guinea (which went from 86 to 103 deaths per 1,000 live births).

Figure C1.2 reports the most recent cross-section of under-5 mortality rates used to calculate the 2020 HCI. Child mortality rates range from around 0.002 (2 per 1,000 live births) in the richest countries to around 0.120 (120 per 1,000 live births) in the poorest countries.
**Figure C1.2: Under-5 mortality rates, HCl 2020**

Notes: The figure plots under-5 mortality rates (on the vertical axis) against log GDP per capita at 2011 USD PPP (on the horizontal axis).

**Figure C1.3: Sex-disaggregated under-5 mortality rates**

Notes: The figure plots sex-disaggregated under-5 mortality rates. The solid dot indicates the national average, the triangle is used to show the average value for girls, and the horizontal line shows the average value for boys.
Under-5 mortality rates tend to be slightly lower for girls than for boys, as reported in figure C1.3. In the figure, the solid dot indicates the country average, the triangle indicates the average for girls, and the horizontal bar indicates the average for boys. The average under-5 mortality rate for boys was 0.03 (30 deaths per 1,000 live births), compared to 0.025 for girls.

Figure C1.4 reports average child mortality rates by income group and by World Bank region. Mortality rates tend to be highest in low-income countries, and regional averages are highest in Sub-Saharan Africa and South Asia, reflecting that poor countries continue to bear a disproportionate burden of child mortality.

2. **EXPECTED YEARS OF SCHOOL**

The expected years of school (EYS) component of the HCI captures the number of years of school a child born today can expect to achieve by age 18, given the prevailing pattern of enrollment rates in her country. Conceptually, EYS is simply the sum

---

15 This section borrows heavily from the Technical Appendix of Kraay (2018).
of enrollment rates by age from age 4 to 17. Because age-specific enrollment rates are not broadly or systematically available, more readily-available data on enrollment rates by level of school are used to approximate enrollment rates in different age brackets. Pre-primary enrollment rates approximate the enrollment rates for 4- and 5-year-olds, primary enrollment rates approximate for 6- to 11-year-olds, lower-secondary rates approximate for 12- to 14-year-olds, and upper-secondary rates approximate for 15- to 17-year-olds. Cross-country definitions in school starting ages and the duration of the various levels of school imply that these will only be approximations of the number of years of school a child can expect to complete by age 18.

Given that the objective is to obtain a close proxy to age-specific enrollment rates, the preferred measure is the “total net enrollment rate” (TNER). TNER measures the fraction of children in the theoretical age range for a given level of school who are in school at any level. For many countries, the TNER is not readily available for all levels and thus, in many instances, less preferred rates are used. The order of preference for the use of enrollment rates is:

1. Total net enrollment rates (TNER): TNER measures the fraction of children in the theoretical age range for a given level of school who are in school at any level. For pre-primary, because there is no level before pre-primary, TNER is not available, and ANER is the preferred measure.
2. Adjusted net enrollment rates (ANER): ANER measures the fraction of children in the theoretical age range for a given level of school who are in that level or the level above.
3. Net enrollment rates (NER): NER measures the fraction of children in the theoretical age range for a given level of school who are in that level of school.
4. Gross enrollment rates (GER): GER measures the number of children of any age who are enrolled in that given level as a fraction of the number of children in that age range.

The conceptually appropriate enrollment rate to approximate enrollment rates by age brackets is the repetition-adjusted total net enrollment rate. The primary source for enrollment and repetition rates is the United Nations Educational, Scientific, and Cultural Organization’s Institute for Statistics (UIS), revised and supplemented with data provided by World Bank country teams that participated in an extensive data review process. In cases where the resulting data on total net enrollment rates are incomplete, adjusted net enrollment rates, net enrollment rates, or gross enrollment rates are used instead in that order of priority. The same enrollment rate type is used for a given level of education over time.

Because expected years of school is constructed based primarily on administrative data on enrollment rates, uncertainty intervals are not available for this component of the HCI. This does not imply that there is no measurement error, but because it comes

16 The main source for enrollment data from UIS is administrative data. Data are collected by UIS on an annual basis from official national statistical authorities. The data are released in September of every year and include national data for the school or reference year ending in the previous year. The national data are then updated in February, which completes the UIS publication of educational data for the data collection effort of the previous reference year (UIS 2018).
from administrative data there is no error due to modeling or sampling. Consequently, uncertainty in the measurement of expected years of school is not reflected in the uncertainty intervals of the overall HCI.

EYS is calculated as follows:

\[ EYS = \sum_i \text{rate}_i \cdot Y_i; \quad i = \text{pre-primary, primary, lower-secondary, upper-secondary} \]  

where \( \text{rate}_i \) is the enrollment rate for the preferred enrollment type available for that level, and \( Y_i \) is the number of years corresponding to each level.\(^{18}\)

### Enrollment rates for 2020 and 2010

Temporal coverage for enrollment rates is not complete in the UIS public database. Consequently, the first step toward ensuring that the rates used are the most recent and accurate relies on getting inputs from World Bank specialists working on each country to validate and provide more recent values when available.\(^{19}\)

Enrollment rates for 2020 for each school level and for the four enrollment rate types (TNER, ANER, NER, GER) are obtained from UIS.\(^{20}\) Any inputs from World Bank teams working on specific countries are then added to the corresponding enrollment rates. Existing gaps for 2019 in enrollment rates for each level and country are filled by setting the 2019 enrollment rate equal to the latest enrollment rate available for that enrollment rate type. This is referred to as the “carryforward” rule. The rule is applied if the latest available enrollment rate is not older than 10 years.\(^{21}\) This process ensures that the HCI of 2020 and the back-calculated HCI for 2018 are done in a similar way to the first version of the HCI released in 2018. Additionally, enrollment rates are adjusted for repetition, where repetition rates are available, otherwise a repetition rate of 0 is assumed. Finally, enrollment rate types are chosen based on the filled series (that is using the rates for 2019 where gaps have been filled) and based on the following order of preference: TNER, ANER, NER, and GER.\(^{22}\)

In the current HCI update, an effort has been made to also populate an HCI for 2010 using data circa 2010 in addition to data circa 2020.\(^{23}\) Since data collection and availability generally improve over time, enrollment rates for 2010 and older are less likely

---

17 An important agenda concerns the frequent and substantial discrepancies between household survey–based measures of school enrollment and administrative records. D’Souza, Gatti, and Kraay (2019) discuss these briefly.

18 \( Y = 2 \) for pre-primary, \( Y = 6 \) for primary, \( Y = 3 \) for lower-secondary, and \( Y = 3 \) for upper-secondary.

19 For the 2020 update this process was conducted between January 29 and April 29, resulting in revised enrollment rates for all levels, which are available in individual country files on https://www.worldbank.org/en/publication/human-capital.

21 The exceptions to this rule are for Fiji, Kiribati, and Kenya, where the most recent data available are pre-2010.

22 Note that one level of schooling may use TNER while another uses NER. However, for a given level of education, the same enrollment type is used over time.

23 This is done for all countries where the same test is available in or close to the specified year.
to be available than more recent rates. This means that the rule from the first edition of
the HCI used to obtain an EYS measure for 2020 and 2018 cannot be applied to obtain
rates for 2010, because it is not possible to apply the carryforward rule for all econo-
mies where comparable data over time for other components of the HCI are available
circa 2010 and circa 2020. Moreover, to allow that (a) the preferred enrollment type is
used for 2020 and that (b) the enrollment rate type for a given grade in a given country
is the same over time, a different rule is applied to fill in the year 2010 to ensure com-
parability over time, to maximize country coverage.

The rule used to produce EYS in 2010 relies on using annualized growth rates and is
implemented as follows for each school level (i.e., pre-primary, primary, lower-second-
ary, and upper-secondary):

1. For the chosen enrollment rate used in 2020, if a 2010 value from the same rate is
available, and this is not the same rate as the one used to fill in 2020, then that value
is used.²⁴

2. If 2010 is still missing, then use the same enrollment type to obtain an annualized
growth rate between the latest year with non-missing rate before 2010 and the ear-
liest (closest to 2010) year with non-missing rate post 2010. Then apply the annu-
alized growth rate \(agr\) to the rate of the most recent year before 2010 \(year\) with
non-missing rate to obtain the rate for 2010:

\[
rate_{2010} = rate_{year} \left(1 + agr_{2010-year}\right)
\]

3. If there is no rate available for the chosen enrollment type before 2010, then annu-
alized growth rates are obtained using GER enrollment rates, which are available
for most countries. Annualized growth rates are obtained between the latest year
with non-missing rates for the year 2010 or before, if 2010 is not available, and the
GER enrollment rate for the same year or after that of the earliest rate post-2010
of the preferred rate. For example, if the preferred rate is a TNER and its ear-
liest value is for 2012, then the annualized growth rate is obtained from GER. The
annualized growth rate from GER is obtained between the first rate available on or
before 2010, and the first year available after or equal to 2012, since the TNER is
available on that year. This rate is then applied backwards to the TNER of 2012 to
obtain a value for 2010.

\[
rate_{2010} = rate_{year} \left(1 + agr_{GER}\right)_{2010-year}
\]

The process described above yields a value for expected years of school in 2010 for 99
out of 114 eligible economies. For the remaining 15 economies, exceptions to the rules
detailed above are determined on a case-by-case basis in order to populate enrollment
rates in 2010.

²⁴ Exceptions are Qatar pre-primary and primary where the same value of 2010 is used.
Gender disaggregation

Gender disaggregation is an important feature of the Human Capital Index. Although the rules presented in the previous section are meant to complete the EYS for both sexes, there are still adjustments required to ensure that EYS values for boys and girls are plausible. These adjustments are necessary because, although a certain enrollment type may be available for both sexes, it may lack sex-disaggregated information. In other instances, it may be necessary to adjust the disaggregated series because both values for each gender are above (or below) those of the combined enrollment rate.

To fill in the sex-disaggregated enrollment rates the following rules are applied:

1. For every year where rates for both genders and the aggregate are available, the male-to-female ratio and the population share of males and females are calculated.
2. For years that are missing a sex-disaggregated rate, the shares and ratios calculated in step (1) from the closest year available in the past (but not more than 10 years back) are used to impute missing values.
3. For the remaining years where the disaggregated enrollment rates for the preferred enrollment type are still missing, the male and female shares and, where available, the male-to-female ratio from GER enrollment rates are used to impute a value.

It is still possible that the rules above, when applied, return inconsistent values, and it is necessary to adjust the disaggregated series when the male and female rates are both larger (or smaller) than the aggregate enrollment rate. In those cases, we adjust the disaggregated enrollment rate to the value that leaves the aggregate rate at the same distance from each of the disaggregated rates.

\[
\begin{align*}
(i) \quad rate_f^* &= rate_{mf} + \frac{rate_{mf} - rate_m}{2} \\
(ii) \quad rate_m^* &= rate_{mf} + \frac{rate_{mf} - rate_f}{2}
\end{align*}
\]

2018 Back-calculated EYS

Data for the 2020 update of EYS rely on data from UIS. UIS releases data in September of each year, and the release is completed in February of the following year. The 2020 February release of enrollment data from UIS is used for the update of EYS.

The latest data release from UIS is complemented with rates obtained by World Bank staff. The updated data provide an opportunity to update EYS values from the 2018 vintage of the HCI to the latest information available to arrive at a back-calculated EYS for 2018. Because the update allows for the calculation of expected years of school where the data may be newer or come from a different enrollment type than what was used in the first vintage of the HCI, the HCI and EYS of the first vintage of the HCI are not comparable to the current vintage of the HCI and EYS.

---

25 World Bank staff working in each country obtain these data from local government sources, for example, the Ministry of Education or National Statistics Office.
Differences between the HCI values of 2018 for the 2020 update and the 2018 vintage values may be due to a combination of three factors:

1. Data are updated in UIS data vintage, or by World Bank staff.
2. Data on enrollment from a more recent year are now available.
3. Different enrollment types may be available. In some cases, it will be possible to move to a more preferred enrollment type, while in others it is necessary to rely on a less preferred enrollment type. The latter may be the case if UIS has removed the series or because the series is too old.

The average absolute deviation between the back-calculated EYS and the one for 2018 is 0.3 years. However, the changes are considerable for many countries (see figure C2.1).

Although the differences between vintages are considerable, these are mostly due to the fact that the EYS measure generated in this round relies on more preferred rates, and/or newer data. For the 2018 back-calculated EYS, the enrollment data for at least one of the levels for 131 economies comes from a more recent year. For 85 economies, the enrollment rates for all levels correspond to a more recent year. In 21 economies, for at least one of the levels, it

---

**Figure C2.1: Comparing original and back-calculated 2018 expected years of school**

*Notes: The figure plots the expected years of school as used in the HCI of 2018 (on the horizontal axis), and the expected years of school used for the back-calculated HCI of 2018 (on the vertical axis). The figure indicates differences that arise due to data updates.*

26 The flip side is that for 15 economies at least one of the enrollment rates used comes from an older year than was available in 2018’s EYS. This is mostly because UIS revises the series, and in some instances, years may be removed from the series.
is necessary to change to a less preferred series. This is mostly in cases where the series has been removed in the update of the data. On the other hand, in 20 countries, for at least one level it is possible to calculate EYS with a more preferred type of enrollment rate.

Figure C2.2 and figure C2.3 present details for countries where EYS under the new data vintage has increased by at least half a year. In most economies where EYS increased by at least half a year there is a move to a data point that is closer to 2018. The exception is for Zimbabwe, where all the enrollment rates correspond to the same year and are for the same enrollment type. In the case of Zimbabwe, the difference is explained as due to the change in the vintage of UIS data. The biggest change for Zimbabwe is observed for primary, where the rate increased by almost 10 percentage points.

A different case to that of Zimbabwe can be observed for Côte d'Ivoire, where every data point comes from a more recent year. However, in this case the difference is also complicated because the previous EYS was built with rates that did not come from UIS but were drawn from government sources by World Bank staff. In the case of Papua New Guinea, the change is due to two factors. Not only are more recent data used for all levels, but also in all but primary the data being used are from a preferred series (figure C2.3). These three countries illustrate the multiple sources for the potential mismatch between the EYS value produced in 2018 and the updated 2018 back-calculated EYS.

Figure C2.4 and figure C2.5 present details for countries where EYS, under the back-calculated 2018 EYS, has decreased by at least half a year. Only in Tanzania is it necessary to move to an older rate, but it is to a preferable type (GER to TNER), and it is only one year older (figure C2.4 for year, and figure C2.5 for types). In Bangladesh, the change in EYS is mostly driven by changes in pre-primary and lower-secondary. For pre-primary, the back-calculated rate relies on data from 2017 versus 2011, although it is for a less preferred rate (GER versus ANER). Meanwhile, for lower-secondary the rate for the back-calculated EYS is for a more recent year but a less preferred rate (ANER versus TNER). In this case, it is necessary to move to a less preferred rate because the TNER series is no longer available in the UIS data vintage for years after 2010.

In India, because the latest available TNER series in UIS is for 2013, World Bank staff has sourced more recent data. EYS is now built with age-specific enrollment profiles that make use of information from UDISE+ from the Ministry of Human Resource Development, as well as early childhood care and education enrollment from the Ministry of Women and Child Development and Entrepreneurship and population projections from the Ministry of Health and Family Welfare. The resulting EYS for the back-calculated HCI is 10.8 versus 10.2, which was used in the calculation for the 2018 HCI.

Figure C2.4 and figure C2.5 should present enough evidence against the comparison of the 2018 HCI published in 2018 and the update of the HCI in 2020. For a more detailed look into the differences, table C2.1 presents enrollment data for all the countries where the absolute EYS change between the back-calculated 2018 and the 2018 versions of the index is greater than half a year.

Notes: The figures plot the enrollment type used for calculation of EYS. Solid dots represent the data used for the back-calculated HCI of 2018, and the x’s indicate the data used for the calculation of the 2018 HCI.
The 2020 EYS shows a high rank correlation to the EYS from 2018, suggesting that the higher a country’s 2018 ranking in EYS, the higher the ranking in EYS in 2020 and vice versa. Also, there is a strong positive relationship between the 2020 EYS and log GDP per capita (figure C2.6).

Expected years of school tend to be slightly higher for girls than for boys, as reported in figure C2.7. In the figure, the solid dot indicates the country average, the triangle indicates the average for girls, and the horizontal bar indicates the average for boys. The average expected years of school for boys was 11.3 compared to 11.4 for girls. Disparity in expected years of school is lower in richer countries.

Figure C2.8 reports average expected years of school by income group and by World Bank region. Expected years of school tend to be lowest in low-income countries, and regional averages are lowest in Sub-Saharan Africa and South Asia. This suggests that much work remains to be done to close the gap in low-income countries.
Figure C2.7: Sex-disaggregated expected years of school

Notes: The figure plots sex-disaggregated expected years of school. The solid dot indicates the national average, the triangle is used to show the average value for girls, and the horizontal line shows the average value for boys.

Figure C2.8: Expected years of school by income group and region

Notes: The figures plot regional and income group average values for expected years of school.
3. HARMONIZED TEST SCORES

The school quality adjustment is based on a large-scale effort to harmonize international student achievement tests from several multicountry testing programs to produce the Global Dataset on Education Quality. A detailed description of the test score harmonization exercise is provided in Patrinos and Angrist (2018), and the HCI draws on an updated version of this dataset as of January 2020.27 The dataset harmonizes scores from three major international testing programs—the Trends in International Mathematics and Science Study (TIMSS) program, the Progress in International Reading Literacy Study (PIRLS), and the Programme for International Student Assessment (PISA)—as well as three major regional testing programs—the Southern and Eastern Africa Consortium for Monitoring Educational Quality (SACMEQ), the Program for the Analysis of Education Systems (PASEC), the Latin American Laboratory for Assessment of the Quality of Education (LLECE), and the Pacific Island Learning and Numeracy Assessment (PILNA). It also incorporates Early Grade Reading Assessments (EGRAs) coordinated by the United States Agency for International Development.

The harmonization methodology relies on the production of an “exchange rate” between international student achievement tests and their regional counterparts, which can then be used to place tests on a common scale. Test scores are converted into TIMSS units as the numeraire, corresponding roughly to a mean of 500 and a standard deviation across students of 100 points. The exchange rate is based on the ratio of average country scores in each program to the corresponding country scores in the numeraire testing program for the set of countries participating in both the numeraire and the other testing program. For example, consider the set of countries that participate in both the PISA and the TIMSS assessments. The ratio of average PISA scores to average TIMSS scores for this set of countries provides a conversion factor for PISA into TIMSS scores that can then be used to convert the PISA scores of all countries into TIMSS scores. The exchange rate is calculated pooling all overlapping observations between 2000 and 2017 and is therefore constant over time. This ensures that within-country fluctuations in harmonized test scores over time for a given testing program reflect only changes in the test scores themselves and not changes in the conversion factor between tests.28 The most recent update of the dataset also uses the 2000–17 period to calculate exchange rates, so that the rates between testing programs do not change between the 2018 and 2020 versions of the database.

2020 Update

The 2020 update of the Global Dataset on Education Quality extends the database to 184 countries and economies, drawing on a large-scale effort by the World Bank to collect learning data globally.

27 For the latest updates on the HTS see Angrist et al. (2019).
28 The one exception to this is the 2007 and 2014 PASEC rounds, which were not designed to be intertemporally comparable and in which different overlapping countries were used to construct the exchange rate in the two periods.
Updates to the database come from new data from PISA 2018, PISA for Development (PISA-D), PILNA, and EGRA. The database adds 20 new countries (8 using EGRAs, 8 using PILNA, 3 using PISA and PISA-D, and 1 using a national TIMSS-equivalent assessment). This brings the percentage of the global school-age population represented by the database to 98.7 percent. In addition, more recent data points have been added for 94 countries (75 from PISA 2018, 7 from PISA-D, 5 from EGRAs, and 7 from PILNA).

In most cases, the tests are designed to be nationally representative. There are, however, some notable cases in which they are not. In the case of China, extrapolations are needed to arrive at nationally representative estimates, since only a small number of relatively affluent regions have participated in PISA assessments. For India, the only internationally comparable assessment is the 2009 PISA. Instead, recent national assessment data and exchange rates with international benchmarks derived from the UNESCO Institute for Statistics (UIS) Global Alliance to Monitor Learning (GAML) process are used to estimate a national harmonized test score (HTS). In a number of countries, EGRAs are not nationally representative and are identified as EGRANR in the data documentation.

In cases where countries participate in multiple testing programs, a hierarchy of tests is applied to determine which HTS to use. This hierarchy is based on the strength of the underlying test construction, the number of overlapping countries to produce the exchange rate, and consistency in administration, procedures, and documentation over time. The first HTS choice is an international test like the PISA, TIMSS, or PIRLS. The next-choice HTS is a regional test, like LLECE, SACMEQ, PASEC, and PILNA (in that order). Finally, if neither an international nor a regional test is available, a country is assigned an HTS that comes from an EGRA. The one exception to this rule is Yemen, where TIMSS data from 2007 and 2011 yield implausibly low scores and are replaced with EGRA data from 2011.

Uncertainty intervals for HTSs are constructed by bootstrapping. Patrinos and Angrist (2018) take 1,000 random draws from the distribution of subject-grade average test scores for each test in their dataset. They then form exchange rates and calculate HTSs in each bootstrapped sample. The 2.5\textsuperscript{th} and 97.5\textsuperscript{th} percentiles of the distribution of the resulting HTSs across bootstrapped samples constitute the lower and upper bounds of the uncertainty interval for the HTS. Test scores are harmonized by subject and grade and are then averaged across subjects and grades.

---

29 For China, the extrapolations are based on the relationship between available internationally comparable test scores and per capita income levels in the regions where these tests were administered, updating the calculations in Annex 4 of Patrinos and Angrist (2018) to include the newly available data from the 2018 PISA round. For India, the methodology takes advantage of a process coordinated by UIS to define common “basic minimum proficiency (BMP)” thresholds across different national and international assessments, including India’s national assessment carried out in 2017. This process creates an equivalence between a BMP threshold in India’s national assessment and the corresponding value in TIMSS/PIRLS. This information is used to rescale the mean scores in India’s national assessment into internationally comparable HTS units. Detailed notes on the methodology and calculations for the HTS for China and India are available on request.

30 For the 2020 HCI, 13 economies have an HTS that comes from a non-representative EGRA: Bangladesh; Central African Republic; Congo, Dem. Rep.; Ethiopia; Iraq; Jamaica; Lao PDR; Liberia; Mali; Myanmar; Nigeria; Pakistan; and South Sudan.

31 See Patrinos and Angrist (2018), for further details.
HTSs for the 2020 HCI come from the most recently available test as of 2019; while data for the back-calculated 2018 HCI come from the most recent test available as of 2017. Data for the baseline comparator year of 2010 are populated for each country using the test closest to 2010, typically with a minimum gap of five years between the test used to populate the 2010 and 2020 cross-sections. Some exceptions to this rule include Bahrain, Botswana, Islamic Republic of Iran, Kuwait, Oman, and South Africa, where data from the 2011 TIMSS or PIRLS are used to calculate the 2010 HCI, and data from the 2015 TIMSS or PIRLS are used to calculate the 2020 HCI. In addition, data for Timor-Leste come from a 2009 and 2011 EGRA, while data for Vietnam come from a 2012 and 2015 PISA for the 2010 HCI, and 2020 HCI respectively.

In order to ensure the comparability of HTSs across time, we ensure that the 2010 and 2020 cross-sections are populated with scores that come from the same testing program. That is, if a country has an HTS from a PISA test circa 2020, it must also have scores from another PISA test circa 2010 to be included in the over-time comparison. The exceptions are Algeria, Morocco, North Macedonia, Saudi Arabia, and Ukraine. For Algeria, harmonized test scores from the PIRLS or the TIMSS in 2007 are used to populate the 2010 HCI, while harmonized test scores based on the PISA in 2015 are used to populate the 2020 HCI. For Morocco, North Macedonia, Saudi Arabia, and Ukraine, data from PIRLS or TIMSS in 2011 are used for the 2010 HCI, while data from PISA 2018 are used for the 2020 HCI. To maximize comparability with PISA, only scores from secondary level schooling are considered for these five countries for the 2010 HCI. Applying these rules yields a sample of 103 countries with test scores in both 2010 and 2020.

Test scores used to produce the back-calculated HCI 2018 are similar to those used in the previous iteration of the HCI, as illustrated in figure C3.1. Data from the two vintages align almost perfectly along the 45-degree line. This is because outcomes for these countries come from the same test and the same harmonization methodology. The figure also highlights the ten countries where test scores have changed because a more recent test was made available in the latest version of the database or, as in the case of China and India, because alternate methodologies were used to refine estimates of national average learning outcomes (see table C3.1 for details on changes in the source of test data). In the case of El Salvador, a choice guided by consultations with the country team was made to replace the previous test used (TIMSS/PIRLS from 2007) with a 2006 LLECE for reading to enhance comparability to the 2018 EGRA (not representative) used in 2020.

Figure C3.2 reports the most recent cross-section of test scores used to calculate the 2020 HCI. HTSs range from around 575 in the richest countries to around 305 in the poorest countries. To interpret these units, note that 400 corresponds to the benchmark of “low proficiency” in TIMSS at the student level, while 625 corresponds to “advanced proficiency.”

Test scores tend to be slightly higher for girls than for boys, as reported in figure C3.3. In the figure, the solid dot indicates the country average, the triangle indicates the average for girls, and the horizontal bar indicates the average for boys. Globally, the average HTS for boys was 420, compared with 430 for girls.
**Figure C3.1:** Comparing original and back-calculated 2018 test scores

*Notes:* The figure plots the harmonized test scores as used in the HCI of 2018 (on the horizontal axis), and the harmonized test scores used for the back-calculated HCI of 2018 (on the vertical axis). The figure indicates differences that arise due to data updates.

Figure C3.4 reports average test scores by income group and by World Bank region. Test scores tend to be lowest in low-income countries, and regional averages are lowest in South Asia and Sub-Saharan Africa.

4. UNDER-5 STUNTING RATES

The fraction of children under 5 not stunted is calculated as the complement of the under-5 stunting rate. The stunting rate is defined as the share of children under the age of 5 whose height is more than two reference standard deviations below the reference median for their ages. The reference median and standard deviations are set by the World Health Organization (WHO) for normal healthy child development. The child-level stunting prevalence is averaged across the relevant 0–5 age range to arrive at an overall under-5 stunting rate. The stunting rate is used as a proxy for latent health of the population, in addition to the adult survival rate, in countries where stunting data are available, as discussed below.

---

Data on stunting rates are taken from the Joint Child Malnutrition Estimates (JME) database, managed by UNICEF, WHO, and the World Bank. The database reports the prevalence of stunting, wasting, and underweight, and is populated with estimates from survey data, gray literature, and reports from national authorities, reviewed by the JME interagency team. If required, data are reanalyzed to produce nationally representative estimates for the appropriate age cohort (0–5 years), comparable across countries and across time. Surveys presenting anthropometric data for age groups other than 0–59 months or 0–60 months are adjusted using national survey results—gathered as close in time as possible—from the same country that include the age range 0–59/60 months. National rural estimates are adjusted similarly using another national survey for the same country as close in time as possible with available national urban and rural data to derive an “adjusted national estimate.” Historical data that use different growth reference standards are reanalyzed to produce estimates based on WHO standards when raw data are available. If raw data are unavailable, estimates are converted to WHO-based prevalence using an algorithm developed by Yang and de Onis (2008).

The JME reports stunting rates from surveys and administrative data and is updated twice a year, in March and September. The HCI team supplements stunting data from the JME with data provided by country teams for five countries: Bhutan, Chile, Fiji, Indonesia, and Timor-Leste. This is primarily to include more recent surveys that have not yet been incorporated in the JME.

The March 2020 update of the JME reports data for 152 countries and 887 country-year observations. About 50 percent of the JME data comes from the Demographic and Health Surveys (DHS) and Multiple Indicator Cluster Surveys (MICS). Both are nationally representative household surveys that collect data on measures of population, health, and nutrition. About 10 percent of JME data comes from country nutrition surveillance programs, while the rest of the database is populated using national surveys that collect anthropometric data and measure stunting directly.

The JME database reports sex-disaggregated stunting rates for 56 percent of the surveys. It also reports 95 percent confidence intervals around estimates of stunting for about 40 percent of the observations, primarily those on which the JME team had access to record-level survey data. Absent better alternatives, the HCI team imputes confidence intervals for the remaining observations in the JME database using the fitted values from a regression of the width of the confidence interval on the stunting rate.

---

35 The DHS program has fielded over 400 surveys across 90 countries, while over 300 MICS have been carried out in more than 100 countries.
Surveys from low- and middle-income countries make up 90 percent of the JME database. High-income countries tend to have much lower average stunting rates (the national average for the 13 high-income countries in the JME sample is 6 percent) and are less likely to regularly monitor stunting through frequent surveys. However, some high-income countries like Kuwait, Oman, and the United States continue frequent monitoring of stunting prevalence through national surveys. Inconsistent measurement is of greater concern in middle- or low-income countries where stunting rates continue to be elevated. The most recent survey for 33 countries in the JME database is more than five years old, and it is around 10 years old for 10 countries. On the other hand, countries like Peru and Senegal elected to field DHS surveys annually. The continuous DHS played a key role in Peru’s national strategy for early childhood development, Crecer, which helped reduce the country’s rate of chronic malnutrition from 28 percent in 2005 to 18 percent in 2016, with an even pace of change among rural and urban children. In the JME data, the average gap between surveys for countries with at least two surveys is 5.6 years, and five years when high-income countries are excluded.

2020 Update
Stunting rates for the 2020 update of the HCI come from the March 2020 update of the JME database, available at the UNICEF website, https://www.who.int/publications-detail/jme-2020-edition. Relative to the 2018 edition of the HCI, this latest update to the database allows us to update stunting rates for 54 countries, and add stunting rates for Argentina, Bulgaria, and Uzbekistan, which did not have a rate in the previous iteration of the HCI.

Stunting rates for the 2020 HCI come from the most recently available survey as of 2019, while data for the back-calculated 2018 HCI come from the most recent survey available as of 2017. Data for the baseline comparator year of 2010 are populated for each country using the survey closest to 2010 that was fielded between 2005 and 2015. When populating the 2010 cross-section, we ensure a minimum gap of five years between the survey used to populate the 2010 and 2020 cross-sections. To maximize the overlap among the three cross-sections, we do not rely on stunting rates in the calculation of the HCI for high-income countries, even when stunting data are available for some of these countries. This is because stunting rates typically come from surveys that are 5–10 years old for these countries. Further, to ensure consistency across time periods, we only use stunting data to calculate the HCI for a country if such data are available in both 2010 and 2020. This does not prevent the calculation of an HCI score for high-income countries or countries missing stunting in any period; we simply use the adult survival rate as the proxy for latent health in our calculations.

Values for stunting rates used to produce the back-calculated HCI 2018 are very similar to those used in the previous iteration of the HCI, as illustrated in figure C4.1, where

---

36 Marini and Rokx (2017).
data from the two vintages align almost perfectly along the 45-degree line. The figure highlights 8 countries where stunting rates have changed by 3 percentage points or more in the back-calculated HCI 2018 versus the original HCI 2018. This is predominantly because the March 2020 update of the JME makes a more recent survey available or, in the case of Djibouti and Sierra Leone, because JME estimates have been updated following a reanalysis of survey data (see table C4.1).

Figure C4.2 reports the most recent cross-section of stunting rates used to calculate the 2020 HCI. Stunting ranges from around 2.5 percent in the richest countries in the sample to around 54 percent in the poorest countries.

The levels of stunting tend to be slightly lower for girls than for boys, as reported in figure C4.3. In the figure, the solid dot indicates the country average, the triangle indicates the average for girls, and the horizontal bar indicates the average for boys. The average stunting rate is 24 percent for boys, compared with 22 percent for girls.

Figure C4.4 reports average stunting rates by income group and by World Bank region. Levels tend to be highest in low-income countries, and regional averages are highest in Sub-Saharan Africa and South Asia.
Stunting rates have seen only modest declines in the last 10 years. Figure C4.5 plots stunting rates in 2020 (on the vertical axis) against rates in 2010 (on the horizontal axis). Of the 42 countries with stunting rates in both 2010 and 2020, roughly 85 percent saw a decrease in stunting (appearing below the dashed 45-degree line), while the remaining
**Figure C4.3: Sex-disaggregated stunting rates**

Notes: The figure plots sex-disaggregated stunting rates. The solid dot indicates the national average, the triangle is used to show the average value for girls, and the horizontal line shows the average value for boys.

**Figure C4.4: Stunting rates by income group and region**

Notes: The figures plot regional and income-group average values for stunting. Only two high-income countries have stunting data, Brunei Darussalam and Barbados.
15 percent saw increases. The average stunting prevalence in this group of countries dropped from 29 percent in 2010 to 24 percent in 2020. Countries with the largest declines in stunting rates include Eswatini, where rates went down by 14 percentage points (from 40 percent to 26 percent), and India, which experienced a 13-percentage-point decline (from 48 percent to 35 percent). On the other hand, stunting rates in Angola went up 9 percentage points, from 29 percent to 38 percent.

5. ADULT SURVIVAL RATES

The adult survival rate is calculated as the complement of the mortality rate for 15- to 60-year-olds. The mortality rate for 15- to 60-year-olds is the probability of a 15-year-old in a specified year dying before reaching the age of 60 if subject to current age-specific mortality rates. It is frequently expressed as a rate per 1,000 alive at 15, in which case it must be divided by 1,000 to obtain the probability of a 15-year-old dying before age 60.

Adult mortality rates are estimated based on prevailing patterns of death rates by age and are reported by the United Nations Population Division (UNPD) for five-year periods. The five-year data are interpolated to arrive at annual estimates to calculate the HCI. The measurement of adult survival rates requires data on death rates by age.
While these are readily available in countries with strong vital registries, such data are missing or incomplete in roughly the poorest quarter of countries. In these countries, the United Nations Population Division estimates death rates by age by linking the limited available age-specific mortality data with model life tables that capture the typical pattern in the distribution of deaths by age.

UNPD does not individually report adult mortality rates for countries with less than 90,000 inhabitants. For this reason, data from the UNPD are supplemented with adult mortality rates from the Global Burden of Disease (GBD) project, managed by the Institute of Health Metrics and Evaluation (IHME). Data from this source are used for Dominica and the Republic of the Marshall Islands. Data for Nauru, Palau, San Marino, St. Kitts and Nevis, and Tuvalu come from the World Health Organization (WHO).

While there is uncertainty on the primary estimates of mortality as well as the process for data modeling, uncertainty intervals are not reported in the UNPD data. Here we use uncertainty intervals reported in the GBD modeling process for adult survival rates. The point estimates for adult survival rates in these two datasets are quite similar for most countries. The ratio of the upper (lower) bound to the point estimate of the adult survival rate in the GBD data is applied to the point estimate of the adult survival rate in the UNPD and WHO data to obtain upper (lower) bounds.

2020 Update

Data for five-year periods from the UNPD are interpolated to arrive at annual estimates. Data from the GBD and WHO are carried forward up to 10 years to fill gaps in the series. UNPD adult mortality rates for the 2020 HCI come from the most recently available year, as of 2019, while data for the back-calculated 2018 HCI come from 2017. Data for the comparator year of 2010 come from 2010. For countries with data from the GBD, the latest data from 2017 are used to populate the 2020 and back-calculated 2018 rates. For countries with data from the WHO, the most recent estimate to populate the 2020 and back-calculated 2018 rates comes from 2012.

Since adult mortality rates are estimated by modeling all available data on adult mortality from vital registration systems, population censuses, household surveys, and sample registration systems combined with model life tables, every new release of data from

---

the UNPD and GBD updates estimates for all the previous years in the time-series. As a result, data for the same year might differ slightly across updates.

Values for adult mortality rates used to produce the back-calculated 2018 HCI are similar to those used in the previous iteration of the HCI, as illustrated in figure C5.1, where data from the two vintages align closely along the 45-degree line for most countries. The figure highlights the 10 countries where adult mortality rates have changed by 30 deaths per 1,000 15-year-olds or more. The largest changes were for Angola (which went from 236 to 279 deaths per 1,000 15-year-olds) and Kazakhstan (which went from 203 to 158 deaths per 1,000 15-year-olds).

Figure C5.2 reports the most recent cross-section of adult mortality rates used to calculate the 2020 HCI. Rates range from around 0.039 (39 deaths per 1,000 15-year-olds) in the richest countries to around 0.477 (477 deaths per 1,000 15-year-olds) in the poorest countries.

Adult mortality rates tend to be lower for women than for men, as reported in figure C5.3. In the figure, the solid dot indicates the country average, the triangle indicates the average for women, and the horizontal bar indicates the average for men. The average
**Figure C5.2: Adult mortality rates, HCI 2020**

Notes: The figure plots adult mortality rates (on the vertical axis) against log GDP per capita at 2011 USD PPP (on the horizontal axis).

**Figure C5.3: Sex-disaggregated adult mortality rates**

Notes: The figure plots sex-disaggregated adult mortality rates. The solid dot indicates the national average, the triangle is used to show the average value for girls, and the horizontal line shows the average value for boys.
adult mortality rate for men was 0.183 (183 deaths per 1,000 15-year-olds), compared to 0.120 for women.

Figure C5.4 reports average adult mortality rates by income group and by World Bank region. Mortality rates tend to be highest in low-income countries, and regional averages are highest in Sub-Saharan Africa and South Asia, reflecting that poor countries continue to bear a disproportionate burden of adult mortality.

6. WORLD BANK-WIDE DATA REVIEW PROCESS AND QUALITY ASSESSMENT

The component data of the Human Capital Index 2020 was subject to extensive Bank-wide data review to ensure data timeliness and quality. The review process was conducted between February and July 2020, and was split into two parts. The first part of the data review process (February to May 2020) focused on the enrollment data used to construct estimates of expected years of school and was done by World Bank Program Leaders for Human Development. The second part of the data review process (May to July 2020) focused on the other four index components—child mortality, harmonized test scores, stunting rates, and adult mortality. The enrollment data was validated separately since experience from the first edition of the HCI in 2018 suggested that it required the most intensive review in terms of time and inputs needed from World Bank country teams due to extensive gaps in the data as reported by the UNESCO Institute for Statistics. All component data was reviewed for timeliness and completeness, with gaps filled and revisions made as needed.

</table>

Notes: This table reports the components and overall index scores for the Human Capital Index 2020, the back-calculated HCI 2018 and the HCI 2010. The Human Capital Index ranges between 0 and 1. The index is measured in terms of the productivity of the next generation of workers relative to the benchmark of complete education and full health. An economy in which a child born today can expect to achieve complete education and full health will score a value of 1 on the index. Empty cells indicate missing data.
